Norwegian University of Science and Technology  
email: kaiolae@idi.ntnu.no

## Abstract

In this paper we study age-varying plasticities across different components in an artificial neural network performing a reinforcement learning task. An evolutionary algorithm is given the task of mapping the age of agents to the plasticity levels of different network components. The results show that patterns of plasticity resembling biological sensitive periods appear, and that these periods schedule learning across the components of the network, which leads to a reduction in the total learning effort while retaining the quality of learning. The sequencing of sensitive periods forms a cascade of partially-overlapping learning periods, which has been proposed as a way of organizing sensory development of abilities that depend on several interrelated brain functions.

## Introduction

Periods in the life of an individual where environmental stimuli are of particular importance for the development of a certain ability are called *critical periods* or *sensitive periods*. They were originally called critical periods to emphasize how lack of the correct stimuli would lead to the sensory system not developing as in normal individuals. In other words, the sensory input is *critical* for neural development. Hubel and Wiesel's classic paper (Hubel and Wiesel (1970)) illustrates this: One eye of a kitten was sutured in various periods throughout life, and it was found that visual deprivation of one eye early in life prevented it from following the regular path of development, leaving the cat blind in that eye, even when it was opened later in life. The period where sutures had this effect was found to have a very specific beginning and end (about four weeks and three months of age, respectively), and this finding is typical of how a critical period was interpreted: A time period with a strict beginning and end, where sensory stimuli have large effects on neural development, and where sensory deprivation leads to abnormal development.

Later research (see for instance Lewis and Maurer (2005)) has shown that sensory systems have *several* critical periods that affect different parts of the sensory system at different stages of development. It has also been shown that these periods can be flexible, and their timing may be controlled by

*experience* rather than age. For example, dark-reared kittens can have the ending of their critical period for vision delayed due to the lack of visual stimuli (Trotter et al. (1981)). These findings have led many researchers to adopt the term *sensitive period*, to emphasize that the period shows a great deal of variation a) across *individuals* that have different experiences during development, b) across *sensory systems* in the same individual and c) across *different parts of a single sensory system*.

An example of the last type of variation was studied by Harwerth et al. (1986). The authors studied the effect of monocular deprivation on different visual functions in rhesus monkeys to investigate the timing of sensitive periods of different functions within a single sensory system. They found there to be *several partially-overlapping* sensitive periods within the visual system, and basic functions (such as spectral sensitivity) were found to have shorter sensitive periods than more complex functions (such as binocular vision). Knudsen (2004) suggests that this property is likely to be found also in other parts of cognitive development, such as in the development of language and social skills. It is logical that low-level behaviors should finish their sensitive period before high-level behaviors, because the low-level outputs will be noisy until these systems have matured, and it will not be possible for the high-level systems to learn from these noisy signals.

Werker and Tees (2006) reviewed findings about sensitive periods in speech processing. The authors argued that speech processing, like vision, depends on a number of inter-related, *hierarchically ordered* brain functions. Based on a review of studies in language development, the authors suggested a possible way for different levels of language learning to be organized through development, where low-level functions once again tend to stabilize before higher-level functions can initiate their sensitive period. Figure 1 shows how they envisioned a *cascade* of sensitive periods in speech processing.

We will mainly use the term *sensitive period* for the remainder of the paper. The term is meant to refer to a period of *heightened plasticity* and sensitivity to environmen-

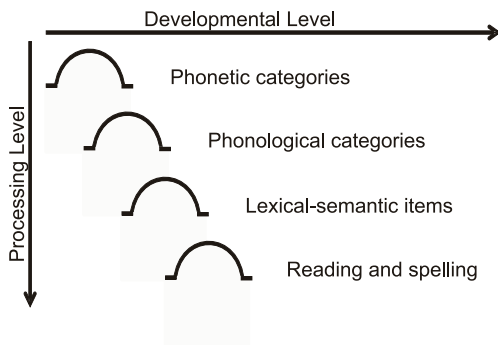

Figure 1: Sensitive periods in speech processing, as suggested by Werker and Tees (2006).

tal stimuli for a given function. If we want to emphasize that the period has a strict ending and that there is no plasticity outside the period, we will use the term *critical period*.

## Background

### Factors behind sensitive periods

Much work has been done in studying which factors *drive* sensitive periods. Armstrong et al. (2006) reviewed some of this work, pointing out two categories of changes that govern their initiation and termination: genetically-mediated changes and experientially-mediated changes. In the former category, sensitive periods will begin and end at a predetermined age as a consequence of innate traits. The latter category concerns factors affecting sensitive periods differently depending on the individual's sensory-input history. Hensch (2005) reviews findings regarding sensitive-period plasticity in the primary visual cortex. He shows evidence from genetically altered mice that the sensitive period in this part of the visual pathway is related to the maturation of *inhibitory circuits*.

Johnson (2005) presents three views on what causes plasticity to decrease as a sensitive period ends: (a) Maturation changes, (b) self-termination of learning, and (c) stabilization of the constraints of plasticity. The first explanation describes chemical processes in the brain that terminate learning independently of experience. The second explanation describes how the learning itself may lead to a decrease in plasticity. One example of a factor leading to self-termination of learning is limited computational resources: when a lot has been learned, there is simply not the same capacity for adding new knowledge. The third explanation regards how sensitive periods may end due to a stabilization in external factors, such as bodily growth, rather than an actual decrease in plasticity.

### Sensitive periods in food preference formation

The experiments in this paper use food-preference formation as the domain for studying sensitive periods. The reason is

that this domain gives us a natural way of splitting the learning task into several subtasks at different levels in a hierarchy, each depending on subtasks below. This is essential if we hope to observe sensitive periods forming in a cascading manner.

Sensitive periods in food preference learning have been studied among animals, for instance snapping turtles (Burghardt and Hess (1966)), lynx spiders (Punzo (2002)) and cuttlefish (Darmaillacq et al. (2006)). Also among human children, a sensitive period of food preference learning has been suggested (Cashdan (1994)).

### Evolving sensitive periods

Bullinaria (2003) studied sensitive periods of learning, as part of a simulation of the human oculomotor system. By the use of an evolutionary algorithm, *age-dependent neural plasticity* was generated. The type of age-dependent plasticity arising from these experiments had parallels with biological sensitive periods. The evolved sensitive periods had the effect of letting individuals be plastic as their sensory systems underwent development, and less plastic after their development was done. Bullinaria describes two simplifying assumptions made in this work that will be important to address in the future. First, plasticities are fully determined by the genotype, meaning *experience* has no effect on the mapping from age to learning rates. Second, the evolved age-dependent plasticity is the same for all parts of the network. In this paper, we remove the second simplification, to study the effect of different evolved learning rates on different parts of an agent's behavior. In a later paper (Bullinaria (2009)) Bullinaria found that a longer period of parental protection gave a lengthening of learning periods in children.

Kirby and Hurford (1997) studied *incremental learning* in language acquisition. By using an evolutionary algorithm to decide the timing of increments to learning capacity, they aimed to study *when* and *why* sensitive periods would form as an effect of incremental learning abilities. They enabled their evolutionary algorithm to shape incremental learning in two ways. It could determine learning resources on the basis of the *age* of an individual or the *experience level* of the individual. Kirby and Hurford found that evolving learning resources based only on the age of an individual gave extreme sensitive periods, similar to what has traditionally been called *critical periods*: A slight delay in the expected stimuli made individuals miss the evolved window for learning, unable to learn language at all. Evolving resources based only on the experience level of an individual gave the opposite effect: No sensitive periods were formed at all – experience could be postponed indefinitely and learning would proceed as normal. It was finally found that letting evolution *combine* the two forms of learning control would give sensitive periods similar to the ones seen in language acquisition in humans.

Hurford (1991) set up an evolutionary algorithm to model

Figure 2: A model of neuromodulated plasticity. The activity of modulatory neurons affects the plasticity of connections between regular neurons.

*language acquisition*. This is a task suggested to have a sensitive period, based on findings from, among other, language recovery in children and adults suffering from aphasia. The evolved learning efforts showed plasticity of the language system peaking in the first period of the individual's life, and gradually falling off to zero. Hurford hypothesizes that the ending of the sensitive period is not happening because it is beneficial to turn off language learning. Rather, as individuals master the language fully at a young age, the pressure to boost language learning is simply gone, so there is no pressure to drive the sensitive period into adulthood. This hypothesis is strengthened by the observations that individuals subjected to a high chance of “language amnesia” at some stage in life tend to evolve lifelong sensitive periods.

### Neuromodulated learning

In the experiments presented here, we study plasticity regulation *across several modules* of a neural network. To exchange reinforcement signals between these modules, we use *neuromodulated learning*.

Neuromodulated neural networks are networks that include another type of signal in addition to the traditional activity-propagating signals. Fellous and Linster (1998) present a review of work on these kinds of networks, revealing that modulatory signals have been used to affect network function in diverse ways, most of them biologically plausible, or at least biologically inspired.

Of particular interest in this context, is the use of neuromodulation to allow efficient reinforcement learning, as that is the role modulation plays in the experiments presented in this paper. In the model of neuromodulated reinforcement learning we employ (Figure 2), modulatory neurons affect the *plasticity* of connections between regular neurons. A single modulatory neuron affects all connections in a *link*, a concept which will be defined in the experimental setup-

section. The model we used is similar to that used in (Soltoggio et al. (2008)), which allowed an agent to learn from sparse events, by letting the modulatory signals have a multiplicative effect on neural plasticity.

### Research Questions

The experiments discussed herein study the emergence of sensitive periods in simple agents in an ALife environment. The environment was set up with a “hierarchical” learning task, where learning of high-level behaviors is dependent on the low-level behaviors already being stable. An evolutionary algorithm (EA) was used to search for optimal sensitive periods for different behaviors. The questions we want to answer are:

- Will the agents show sensitive periods that sequence learning in order of the complexity of behaviors (from low-level to high-level)?
- Will the evolved sensitive periods be able to reduce the agents' learning efforts, while still allowing them to learn the correct behavior?

### Experimental Setup

#### SEVANN

To evolve neural networks with age-varying plasticity, the system SEVANN (Script-Based Evolution of Artificial Neural Networks) (Downing (2010)) was used. SEVANN is a system that lets the user form an *underspecified script* defining an ANN, and then searches for good values for the unspecified parts by use of an evolutionary algorithm. For the experiments reported here, the architecture and initial weights of the ANN were fully specified in the scripts, to allow SEVANN to focus on evolving plasticity values through life, and to allow analyses of results to only depend on the plasticity.

In SEVANN, networks consist of *layers* and *links*: Layers are a number of *neurons* that share common attributes, as well as common inputs and outputs. Links are a number of *arcs* (single connections between neurons) that are grouped together, because they have common attributes, and connect the same layers. When working with age-varying plasticities, we encode learning rates on the link level, allowing evolution to differentiate learning rates between links, but not between single arcs within a link. This granularity was chosen because different links learn different behaviors, and thereby we may allow the sensitive periods to *sequence* behavior learning.

#### Food-Gathering Task

To study how sensitive periods may evolve to sequence the learning of several behaviors, a task with dependencies between different behaviors is needed. The task must have

different levels of behavior, where one level affects performance of the level above - this way, a *cascade* of sensitive periods, as suggested by Werker and Tees (2006), may emerge as a solution to the problem.

Agents are placed on a toroidal grid with food and poison randomly scattered around. To make the hierarchy of behaviors more complex, food is placed in *nuts*, which need to be cracked open to access the food inside. So, the agent has to make three kinds of decisions: where to navigate, which nuts to open, and which food elements to eat. The decisions depend upon each other in a bottom-up fashion: To learn which nuts to open, the agent must first have understood which foods are healthy, then link these to the nuts containing them. And to learn which nuts to navigate to, the agent must first have learned which nuts it wants to open.

Eating food, opening food nuts and visiting food locations increases the agent's fitness, whereas eating poison, opening poison nuts and visiting poison locations decreases it by the same amount. The layout of the food-gathering grid was randomly initialized in each fitness evaluation, with a given probability of each cell containing a poison nut, a food nut or nothing.

An agent resulting from a successful run of the EA typically opens all food nuts and eats all foods. It eats one or a few poison items before learning these should be avoided. Thereafter it still *opens* poison nuts until it learns they are associated with poisons. Next, it passes over poison nuts without opening them, before finally learning to steer away from poison nuts. The order of learning here reflects the hierarchical ordering of the task, and sensitive periods are expected to form in the same order. Each individual was tested *five times* during each fitness evaluation, on grids with different positions of food and poison. This was done to make agents form *general* sensitive periods, instead of sensitive periods adapted to one particular environment.

### Food-Gathering Network

The network structure was chosen to enable learning to propagate from “low-level” (food preferences) to “high-level” (movement preferences) behaviors. The network structure is depicted in Figure 3. It utilizes *neuromodulatory neurons* to be able to transfer what it learned at lower levels to higher levels.

The network mirrors the hierarchical arrangement of the task: Higher levels of behavior are learned by use of reinforcing signals from lower levels. For instance, to learn which nuts to crack (in the link between **InputNut** and **DecisionCrack**), the output from evaluating food is used as a reinforcing signal, with a delay of one timestep: if the food evaluated in the current timestep is good, the decision to crack the nut in the previous timestep was obviously good, and should be repeated in the future. Otherwise, the decision should be avoided, and the arc causing it should weaken.

The bottom layer in each behavior is used to *scale* the out-

Figure 3: The Neural Network that controls food-gathering agents. Rounded rectangles in the figure correspond to **layers** of neurons. Arrows are **links** between the layers. Dotted lines are **plastic links**. Links targeting other links are **modulatory links**, regulating their plasticity. The link ending in a square signifies a negative modulatory activity, whereas the other modulators give positive reinforcement. The plastic links are all initialized with positive values, to facilitate initial exploration.

put activity of that behavior, so that reinforcing modulation on each level is of the same magnitude. Without this scaling, it would be more difficult to compare learning rates across layers, because layers with a very strong modulatory input could learn with a very low learning rate.

### Learning

Arcs in the network are updated by the following learning rule:

$$\Delta w_{ij} = \eta * mod * |x_i x_j| \quad (1)$$

where  $\eta$  is the learning rate, *mod* is the strength of incoming neuromodulation and  $x_i x_j$  is the product of pre-synaptic and post-synaptic activity, in other words a regular Hebbian update term.

As the equation shows, it is the *absolute value* of the hebbian update that is used in the calculation of the new weight value, since we want the *modulatory signal* to decide the direction of the weight change: negative modulation means whatever action was taken was a bad idea, so the weight of the link causing the action should be decreased. Positive modulation should have the opposite effect. In the absence of modulation (in other words, if  $mod = 0$ ), weights are not updated.

The age-dependent learning rate is encoded as a sequence of real values ( $\vec{\eta}$ ) in the genome. One such sequence is evolved for each plastic link in the network. Each value in the sequence describes the *change* in learning rate for the current age. The first value in the sequence encodes the *initial* learning rate for the link. A separate parameter decides the *delta age*,  $\delta_{age}$ , of the link. This parameter tells the algorithm how often it should update its current learning rate. For instance,  $\delta_{age} = 5$  would mean the rate is updated every

Parameter	Value
Generations	100
Adults	30
Children	50
Crossover probability	0.1
Mutation probability	0.005
Genes per individual	75
Bits per gene	8
Elite fraction	0.2
Culling fraction	0.25

Table 1: Parameters of the Evolutionary Algorithm

fifth timestep, giving a total of 20 updates for a 100-timestep run. A reasonable setting of this parameter allows us to reduce the complexity in finding a good mapping from age to plasticity. For the experiments reported here,  $\delta_{age} = 4$ .

For the environment and network presented here, it was found that a range of numbers from -0.25 to 0.25 was a good selection for the available values for  $\bar{\eta}$ . This gave the evolutionary algorithm the opportunity to tune the learning rate quite finely, as well as having the possibility to move fairly rapidly towards high or low rates when needed.

Negative learning rates are not allowed. If the learning rate goes into negative values, it is treated as a learning rate of zero. Still, the negative value of the learning rate is remembered when calculating the learning rate for the next age. This makes it possible for evolution to drive the learning rate far into the negative domain, meaning it can effectively “shut off” learning by adjusting the learning rate. This way, the encoding allows evolution to generate sensitive periods that are quite resistant to disruptive mutations.

## Evolutionary Parameters

Table 1 gives the parameters of the evolutionary algorithm for the experiments reported here. Crossover probability gives the probability of crossover *per individual*, and mutation probability gives the probability of mutation *per bit* in the individuals’ genotype.

The same parameters were used for all runs, except for the case where *static* learning rates were evolved. For these runs, we needed only *three* genes to specify the learning strategy followed by an individual (one gene per learning link). Those three genes were each encoded by 20 bits, to allow evolution to fine-tune the static learning rate. The remaining parameters were not altered.

## Results

### Learning costs and sensitive periods

Figure 4 shows average evolved age-dependent plasticities for the three different behaviors in the task when there is no cost of learning. As expected, no sensitive periods are

Figure 4: Evolved plasticities with no cost of learning. The figure displays the plasticity in the three links of the network as a function of the agent’s age. – Averages over 50 runs. Error bars show one standard deviation.

formed, as there is no pressure to form them imposed by the evolutionary algorithm.

A cost of learning on the fitness of individuals is documented in biology (see for instance Mery and Kawecki (2003) for an example from the common fruit fly). We simulate the costs associated with plasticity to see how this affects the evolution of age-dependent plasticity. The cost of learning is implemented as a term subtracted from an individual’s total fitness. It is proportional to the sum of areas under the agent’s three plasticity graphs.

Figure 5 shows the evolved plasticities when adding this cost to fitness evaluations. As the figure shows, we see cascading sensitive periods moving from lower to higher levels of behavior. Averaging over 50 individuals smooths the sensitive periods, meaning the cascades show more overlap than what is normally present in individuals. We will see later in this section that the evolved plasticities within individuals do show the expected ordering of learning.

Another reason for the large degree of overlap is that the individual behaviors are very simple to learn: they can be learned by a single observation of the relevant association. Had each behavior been more complex, taking more time to learn, it is expected that sensitive periods would be further separated in time.

**Sensory deprivation** A common way of studying sensitive and critical periods, is to subject individuals to sensory deprivation up until a certain age, and study their development after this age. If they are unable to follow a regular path of development, we have an indication that the plasticity of the considered system underwent a critical period before that age. In our deprivation study, we subjected the winner individual of each evolutionary run to sensory deprivation on all three levels of behavior, and measured its performance on the considered behavior. For instance, to test

Figure 5: Evolved plasticities with a cost of learning – Averages over 50 runs. Error bars show one standard deviation

Figure 6: The result of sensory deprivation. – Averages over 50 runs. Dots show measured values, lines interpolate between them.

whether there was a sensitive period for learning about nuts, we waited for a given time before presenting the individual to nut stimuli, and measured how well it was able to learn the nut association task from this age.

Task performance was measured as the amount of correct associations made during the rest of the individuals' life (after finishing sensory deprivation), reduced by the amount of incorrect associations made. An inverse relationship between deprivation length and task performance was observed for individuals with a constant learning rate throughout life, because for longer deprivation lengths, individuals had less time to accumulate performance points.

For individuals allowed to evolve age-dependent plasticity, the sensory deprivation resulted in the task performance shown in Figure 6. All behaviors approach zero for sensory deprivation above a certain age, indicating that learning the associated behavior was not possible after this age. Further, we see the cascading of learning observed in Figure 5 af-

fect the timing of the age when sensory deprivation disrupts further learning.

The fact that performance seems to fall off *gradually* with increasing durations of sensory deprivation is due to differences in the evolved timing of sensitive periods between individuals. Studying single individuals, we observed that the cut off is much more dramatic. In other words, the term *critical period* describes this learning better than *sensitive period*. The reason is of course that *age* is the factor controlling plasticity, so delaying stimuli beyond a certain age will prevent all learning.

## Learning Order

This section presents statistics about the *ordering* of sensitive periods. We evaluated 50 individuals, noting how many of these formed the *expected order* of sensitive periods. The order of sensitive periods was measured by calculating the *center of mass* for plasticity in each behavior, and ordering them in order of ascending center of mass. An early center of mass for a behavior means a lot of learning is going on early in the life of the agent, corresponding to an early sensitive period.

The order of the centers of mass was then compared to the ordering that would be generated by random processes. For three different behaviors, 6 different orderings are possible, and the expected number of times each would be seen is  $1/6 * 50 = 8.33$ . For a statistically significant indication that the expected ordering is preferred, we need to see the expected order of sensitive periods at least 14 times, which is associated with a p-value lower than 0.04. For comparisons between *pairs* of behaviors, we need to see the expected order of sensitive periods at least 32 times, again indicating a p-value lower than 0.04.

Table 2 shows statistics from runs of the experiment with and without a learning cost. The table shows that there is *no significant evidence* that plasticity schedules learning in the expected order, when there is *no cost of plasticity*. However, when individuals are evolved *with* a plasticity cost, they are forced to being more cost-effective, thus scheduling their learning.

**Shuffling** After observing that sensitive periods tended to form in an order from “lower” to “higher” levels of behavior, we wanted to test just how important this ordering was. To do this, we shuffled sensitive periods in each of the winner individuals from our 50 runs of evolution. This was done by extracting evolved learning strategies from one layer, and inserting it into another within the same individual. The resulting individuals were each tested on 50 new mazes, and their average fitness was stored as an indication of how well they were able to learn preferences in these mazes. Notice that shuffling does not affect the learning costs of an individual, so a difference in fitness indicates a difference in learning performance.

Learning Cost	p(F-N-M)	p(F-N)	p(N-M)	p(F-M)
Yes	< <b>0.001</b>	<b>0.008</b>	< <b>0.001</b>	< <b>0.001</b>
No	0.317	0.839	0.556	0.336

Table 2: The ordering of sensitive periods. Letters F, N and M are used to indicate the different learned associations: **F**ood, **N**uts and **M**ovement associations. The following columns show the probability of observing the evolved ordering of sensitive periods by chance, first for all three behaviors, then their pairwise orderings. Results in bold signify statistically significant evidence that evolution prefers to arrange sensitive periods in the expected order. All results were obtained by doing 50 runs of the EA.

Figure 7: How learning is affected by shuffling sensitive periods. – Averages over 50 runs. Error bars show a 95% confidence interval of the mean.

Figure 7 shows the result of the shuffling of sensitive periods. The labels below axes indicate what new ordering of learning the shuffling corresponds to. (Food - Nut - Movement) was the original ordering, so this label indicates no shuffling. We see that increased shuffling gives a decrease in learning ability (seen as a decrease in fitness). Shuffling only two of the evolved sensitive periods, gives less of a fitness decrease than shuffling all three. The lowest fitness is observed when the sensitive periods are completely reversed, indicating that a proper sequencing is essential for learning in the winner individuals.

### The utility of age-dependent plasticity

So far, we have seen how age-dependent plasticity allows the formation of sensitive periods. In this section, we will analyze exactly what is the *utility* of these periods. We will do that by comparing the fitness of evolved agents with static plasticity levels and with plasticity levels that vary throughout life.

Figure 8 shows the fitness of individuals *with* and *without* a plasticity cost. During evolution, the plasticity cost was active in both cases, meaning all individuals evolved to form as cost-effective learning strategies as possible. As the right figure shows, the agents allowed to utilize age-dependent

plasticity become more *cost effective* – their fitness is higher because they pay a lower cost. However, as can be seen in the left figure, this more efficient learning strategy does not degrade their learning ability. When not applying a cost of plasticity, the fitness is only based on what the agents can learn, and this value is not significantly different for the two types of learners.

### Conclusion

In this paper we have shown how sensitive periods in learning can emerge for a reinforcement learning task by allowing an evolutionary algorithm to tune the mapping from ages of individuals to plasticity values. The task to be solved required several levels of interdependent behavior to be learned, and a different age-plasticity mapping was evolved for each level. The evolved sensitive periods showed the ability to *sequence* learning in a bottom-up fashion, allowing the network to learn the simpler behaviors first, before learning the higher-level behaviors that depend upon them.

A condition for observing the sensitive periods was that plasticity had an associated *cost*. This cost made evolution form solutions that learn in a cost-effective way. It is the balance between having the ability to learn while paying as low a cost as possible, that drove evolution to finding *cascading sensitive periods*.

In summary, we have seen how evolved sensitive periods can *sequence* the learning of sub-behaviors, and that the factor that drives this sequencing is achieving a good balance between the costs and benefits of learning. Currently, we are working on extending this model to account for experience as a regulator of plasticity, and to include the possibility of evolved hard-coded preferences.

Another interesting direction for future work is to investigate critical periods in more complicated tasks, perhaps tasks that cannot be solved with a constant learning rate. In other words, tasks that would normally be approached with a different technique such as incremental learning. We believe sensitive periods could be useful in such tasks, because they offer a way of scheduling learning activities between different behaviors.

Finally, the complexity of individual behaviors in the current study is quite low. It would be interesting to see how sensitive periods are affected by scaling up the complexity

Figure 8: Box plots of fitness values calculated with and without plasticity cost. Nonoverlapping box notches indicate significantly different means with a 0.05 significance level. – Averages over 50 runs.

of behaviors, and also how they are affected by tasks where the progress of learning each individual behavior is less predictable.

# Autopoiesis Facilitates Self-Reproduction

Jean Sirmai

Clinician and Hospital Medical Practitioner, Ile de France.

[jean.sirmai@orange.fr](mailto:jean.sirmai@orange.fr)

## Abstract

The first *in silico* models of self-reproduction only focused on the logic of the mechanisms that execute and copy the genome or renew the membrane, but neglected associated physical constraints. This may have resulted from modeling through cellular automata, which are unable to represent the cohesion of objects in movement and interaction. In previous work I presented a new, well structured and powerful tool based on a graph rewriting system embedded in a spatial automaton. This tool employs combinations of a unique symbol and can represent an unlimited variety of moving and interacting objects. As transitions are local and occur at random, each trajectory of the system differs. However, dependent events can always be represented in their natural order.

With this tool, I built a representation of an autopoietic individual. More recently, I hypothesized that this model could also be used to demonstrate self-reproduction because most of the mechanisms required for growth are already available in the autopoietic individual and few additional functions are needed. Here, I report the advancement of the model to demonstrate the ability of the autopoietic individual to self-reproduce. During self-reproduction, autopoiesis remains active and the lifespans of the various components are unchanged.

Pathological morphologies can be observed when some metabolic pathways are disturbed. Using appropriate approximations, some thermodynamic parameters can be evaluated. Additionally, a second autopoietic and self-reproductive individual can be represented within the same environment. Further, the model could be used to describe the space phase domain and invariants characteristics of each of these individuals, whose systematic enumeration and classification can be envisioned. Based on this model, I propose that autopoiesis facilitates self-reproduction.

## Introduction

An entity capable of self-renewal is said to be autopoietic (Maturana and Varela, 1973). Commonly, biological entities (e.g., cells, tissues, societies) are observed to be able to generate almost all the components with which they maintain their structure and functions. I hypothesize that this can result from the association of two independent properties: persistence and cohesion.

Persistence is the property of the entities that are able to maintain their composition while constantly renewing themselves. Under this property, each part of the entity is produced by at least one transformation and destroyed by another; these transformations regulate one another<sup>1</sup>. Such

entities depend on a permanent input and output of energy and materials. The ingoing components are rich in potential energy, while the outgoing components are poor. External components can be classified as resources, neutrals, or toxins. When exposed to a toxin, the whole may be able to compensate for its effects. If it is not and this results in the defect of a major regulatory pathway, it may not remain persistent. It controls its composition, which fluctuates around a mean, but not its shape and size, which depend on the limits provided by its environment. Its lack of cohesion hampers its transfer in another environment. It can split in two persistent entities if each resulting part keeps the initial composition and is provided with input and output pathways, but it cannot control this process and self-reproduce. Conversely two persistent entities of compatible composition in direct contact with each other can merge. Persistence could have been a property of some instances of the “prebiotic soups” imagined by Oparin and Haldane (see Popa, 2004).

A persistent entity is autopoietic if some of its components, other than the entering and outgoing ones, ensure its cohesion. Compared to a simply persistent entity, an autopoietic individual is endowed with several new properties. First, it controls not only its composition but also, at least partly, its limits, inputs, outputs, shape, and size. It can keep its shape longer than the parts composing it can. Second, in so much as its state remains stable, its entropy remains roughly constant while that of its environment increases (Schrödinger, 1944). Third, the more energy is available in its environment the more it controls its use of this energy (Virgo, 2011). Fourth, it can attain a maximal performance in extraction and use of energy from its environment. Conversely, pathological states exist where its global performance is reduced. Fifth, it can be moved and then maintain itself in any non-toxic environment providing only its inputs. Sixth, it can be associated to self-reproduction. Seventh, it loses these properties if split (giving rise to the etymology of the word “individual”). Correlatively, two similar autopoietic individuals in direct contact with each other will not merge (McMullin, 2004). Cohesion can be obtained by including all the components in a compartment. Another possibility would be to link them all together. The existence of such a kind of individual would demonstrate that the presence of an interior milieu is not a necessary condition for autopoiesis.

Prior work has proposed that self-reproduction is a particular case of self-production (Sharov, 1999). In self-reproduction, an individual is able to extract some energy and matter from its environment and use it to produce a new individual that is similar to itself and that remains distinct. Once the reproductive process has been completed the new individual cannot be distinguished from the other by anything but their history. The model I describe here supports the hypothesis that autopoiesis can facilitate self-reproduction and show the details of this process in the case

<sup>1</sup> It identifies each part of itself at least twice: once to synthesise it and once to destroy it. We might assume two relationships exist, such that, 1) the more complex a component, the more efficient it is, and 2) the more complex a component, the more complex the operations required to build or destroy it. Then, because they are constrained to operate constantly on one another, all components of one persistent object will tend to share similar levels of efficiency and complexity.

of self-reproduction by budding. As most of the mechanisms required for growth are already available in an autopoietic individual, few additional functions are needed for this individual to reproduce itself.

Autopoiesis and self-reproduction were first described in bottom-up models (see Discussion). Recently, a first top-down model based on ordinary differential equations was described (Karr et al., 2012). This model is a proof of concept. It shows that some properties of a real living object can be computed. However, not all these properties can be simultaneously represented in detail. This is due to the impossibility of completely isolating an object as well as to a lack of knowledge and of computing power (Zwirn, 2000). Karr's model represents both some biochemical mechanisms (non-biological *stricto sensu*) and some biological properties. These are mainly the reproduction cycle, autopoiesis, and the energetic balance of *Mycoplasma genitalium*. As it uses successive approximations of several sub-models, this model is redundant. The redundancy contrasts with the minimal expression of the same properties in the bottom-up models. However, one can expect that top-down and bottom-up approaches (analytical and synthetical) will converge towards one another (Hucka et al., 2003). Bottom-up models could help to define properties and to extract only the meaningful information relevant for each of them from top-down models.

Anatomical characteristics of life have been beautifully described by Goodsell (see images following References) (2009). His work seeks an integrated view of all the components of a cell. He erases the mechanistic details that would be required for a comprehensive description of all the functions of those components and extracts only those that enable the approximation of the main anatomical and physiological properties of the living. Thus, his drawings inspire this work.

## Methods

The previously described platform associates a graph rewriting system to a spatial automaton and provides a new, well structured and powerful language to represent almost any biological phenomena (Sirmai, 2011)<sup>2</sup>. It can be seen as a new artificial chemistry (Dittrich, 2009) that can apply to any phenomenon characterized by a great variety of forms and interactions. This diversity suggests the use of a combinatorial method. To enable such a possibility, I introduced indexes (previously called "links") in the cells of a spatial automaton. An index belongs to a cell and points to a neighboring one. A set of cells pointing to one another by their indexes is an object. The cells of the state containing indexes then become nodes of a graph and the indexes are the edges. These edges are oriented and weighted, as many indexes can point towards the same neighbor.

Each object is an isolated part of the graph. It is completely described by the location and orientation of the indexes that compose it. This formalism does not limit the size, shape or number of objects. In the present model, no index may designate an empty cell and only adjacent cells can be designated. These parameters could be modified.

Each transition associates a set of conditions to a set of operations. All the conditions are the same type: they test

the number of indexes in a given location and orientation. All operations are of the same type: they move an index from a place to another. This formalism does not limit the variety of movements or transformations that can apply to each object or couple of objects. In the present model, no operation changes the total number of indexes arranged in space or the number of indexes of a cell.

The automaton deals only with indexes in the cells. It uses no conditions on the objects such as a name or a color. Users can recognise the objects drawn using these indexes (Figure 1, left panel) but this recognition is made easier by the use of colors (Figure 1, right panel), as can be seen by comparing the two panels (Fig. 1), which display the same workspace. A second-level language may be superimposed to the first to recognize the objects and enable the user to interact directly with them rather than with the indexes. In the present model, the workspace is a two-dimensional hexagonal matrix without boundaries, wrapped over a torus.

Figure 1: Two views of the same space state.  
Left, indexes alone. Right, colored particles.

The space is not explored using its coordinates but according to its content. Each transition converts only a part of the space. This part is centered by a randomly chosen index. It is then assessed through different sets of conditions. If a set of conditions is satisfied, then the set of associated operations is performed.

All information regarding the description of objects is in the space. All information concerning their movements and interactions is in the transitions. No other information is encoded.

Transitions can move, deform, transport, or transform objects. Displacements, deformations, and transports maintain the objects in the same class. Transformations shift them from one class to another. Each class is associated with some characteristic pattern of indexes that can be identified by some adequate conditions' sets.

Here, interactions are not associated with one object, but with at least two and possibly more. They are thus described only once. The downside is that each transition must identify each object involved (pattern recognition). Each transition can apply to the few neighboring cells representing one object to move or to parts of two objects in interaction and not necessarily to the entire space at one time.

The objects to which transitions apply are chosen at random. Transitions occurring in a random order adequately represent independent events. Yet, it happens that an event depends on another one which determines it, and the determining event always occurs always before the dependent one. In the same way, the transition representing

<sup>2</sup> The open-source program is available at [www.interactor.fr](http://www.interactor.fr).

the determined event must always occur before the transition representing the dependent event. This can be achieved by using an intermediate state, which is the result of the first transition and the beginning of the second. There must be no transition going directly from the initial state of the first transition to the final state of the second. If this rule is followed, the second transition will always occur after the first, although the order in which transitions occur is chosen at random.

Hereafter, the environment will be hidden to concentrate on the description of the individuals. Importantly, some space remains always free in the compartment and outside enabling a permanent random movement of all objects.

## Results

Two individuals will be described: one called “Tiuccia” and the other “Lagny”<sup>3</sup>. When the model is running, Tiuccia is easily recognizable as it is circled in green and Lagny looks like a yellow little worm.

Tiuccia is made of seven varieties of aggregates: five are implied in autopoiesis, two in reproduction. Tiuccia comprises a membrane enclosing an internal compartment. The membrane ensures the cohesion of the whole. It is made of one-index particles pointing each to the next one. Because of its asymmetry (all its indexes are oriented clockwise) its inside and outside faces can always be locally recognized. The internal compartment contains freely-moving tetramers, trimers, and dimers (Figure 2). Trimers and dimers are also present in the environment (not shown in this view). An arbitrarily high potential energy is assigned to the trimers (food) and a low one to the dimers (wastes). The membrane is selectively permeable: trimers can only enter (**te**; See Table 1) and dimers can only exit (**de**). In the environment a mechanism converts permanently dimers in trimers to maintain a favorable condition.

Figure 2: Anatomy. Screen capture of Tiuccia indicates the objects it comprises.

Small chains of one, two, three, or more units long are attached to the internal face of the membrane. When the membrane wrinkles near an attached chain, one of its units can be removed and transformed into a chain unit. This transformation (**mc**) lengthens the chain while the membrane shortens. The membrane's continuity remains

ensured. When a chain is at least four units long, its terminal end can fold in on itself and transform into a tetramer (**ct**). Therefore, the presence of tetramers indicates that some membrane catabolism (destruction) occurred. When the tetramer concentration increases, tetramers catalyse their own catabolism. If three tetramers are adjacent, the central one will be transformed into two dimers (**td**).

When two trimers are close to the membrane, one of them catalyses the transformation (**tc**) of the other into a one-unit chain and a dimer. The one-unit chain is attached to the internal face of the membrane and will lengthen as previously described. The presence of many trimers in the cell is an indicator of a high level of accessible food. This signal initiates membrane catabolism.

When a tetramer and a trimer are close to the membrane, the tetramer catalyses the transformation (**tm**) of the trimer in a unit of membrane and a dimer. The unit is inserted in the membrane. Tetramers are a signal of a previous membrane catabolism and a condition of its anabolism (synthesis).

Because of this coupling of regulation, the size and shape of Tiuccia remain almost constant while all its components are permanently renewed. Inputs and outputs are in competition with the synthesis and destruction of the membrane that regulate its length. Figure 3 and Table 1 depict this metabolism.

Figure 3: Metabolic pathways and their regulations.

## Budding

The “budding” process occurs through ten transformations and transports. Only four of these are specific to reproduction. The other six occur in both autopoiesis and reproduction, and their denominations remain unchanged in the following description.

The first step of budding consists of the capture by the bud of a double-index dimer moving near it in the environment (Figure 4a; budding transformation 1). The bud itself is made of particles containing two indexes. The captured dimer is integrated close to the bud into the membrane and the whole gives rise to a 4-double-index particle sequence: the cord.

<sup>3</sup> From the names of the cities where they were first observed.

Name	Description (effect)	Conditions of realisation and metabolic meaning
te	trimer entry	trimers are present in the environment; free space is available inside the membrane is flexible; no chains are attached locally
tc	one trimer $\rightarrow$ one dimer + new chain (one unit)	presence of another trimer means that a high food content is available the new chain is anchored to the internal face of the membrane
mc	membrane (one unit) $\rightarrow$ chain (one unit)	the membrane must wrinkle towards inside the chain must be attached to that part of the membrane
ct	chain (four units) $\rightarrow$ one tetramer	the chain length is almost four units long it can fold in on itself at random
tm	trimer $\rightarrow$ one dimer + membrane (one unit)	the new unit is inserted in the membrane; this transformation depends on the presence of a tetramer that acts like a catalyst and is left unchanged
td	one tetramer $\rightarrow$ two dimers	two other tetramers are adjacent and act like catalysts
de	dimer exit	free space is available outside; the membrane is flexible no chains are attached to the membrane locally

Table 1: Metabolic pathways. The names refer to the names in figure 3 and in the text.

The cord catalyses the second step (Figure 4b): it captures a tetramer and transforms it in a short membrane fragment (budding transformation 2). This fragment is located outside of the main compartment and attached to it by its two extremities. Tetramers can be found in the cell only and they are a sign of its maturity and good nutritional status. The position of the cord between the two compartments that it both links and separates is asymmetric at its insertions. The main compartment will be called the parent and the smallest the offspring.

The asymmetry enables the cord to specifically catalyse the elongation of the new fragment of membrane starting from trimers provided by the parent (budding

transformation 3). A particle of a parent trimer close to the cord insertion is added to the offspring's membrane. The remaining dimer stays in the parent and will be eliminated later (**de**).

These three transformations are enough to initiate a complete new autopoietic process that enables the growth of the offspring. The next steps are part of the autopoietic process. They occur when the offspring's membrane becomes long enough to absorb trimers (Figure 4c; **te**) and to release dimers (**de**). As soon as two trimers have been absorbed, they can give rise to a one-unit chain (**tc**). As the offspring's membrane keeps growing, due to the parent's assistance, the chain can lengthen (Figure 4d; **mc**).

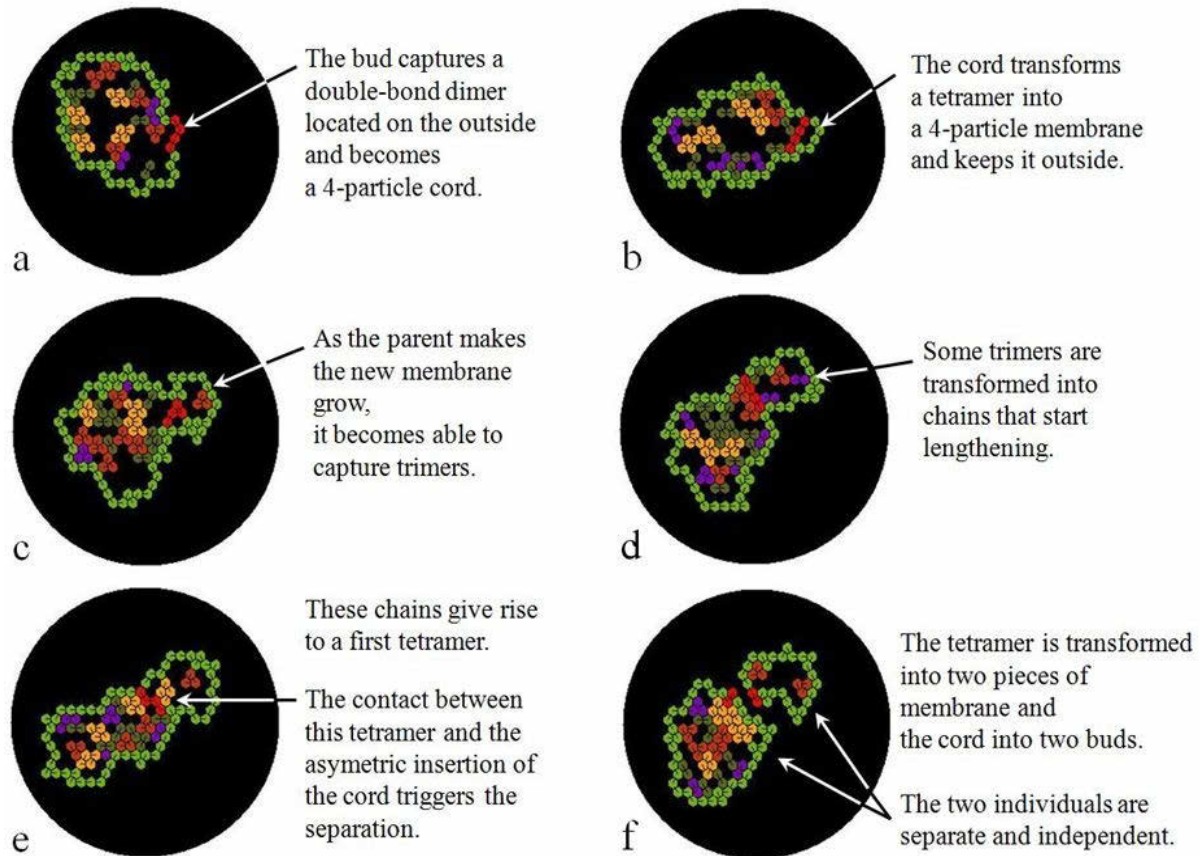

Figure 4: Budding.

Figure 5: Three abnormal morphologies associated each with a different metabolic defect.

When it attains a four-unit length, its transformation in a tetramer becomes possible (Figure 4e; **ct**). The production of a tetramer by the offspring is a signal of maturity. It guarantees that the membrane has grown enough to ensure first its own degradation and second its own production. This signal is recognized by the cord and initiates the separation (Figure 4e; budding transformation 4). The cord divides in two buds of two particles each, one belonging to the parent and the other to the offspring (Figure 4f). These individuals become completely independent.

As an offspring's tetramer is transformed into membrane during the separation, the offspring may be found to have only one tetramer or none at this stage. This feature is characteristic of a young individual and will not persist. Other tetramers will be produced continuously, and, once there are two tetramers, the number will not decrease anymore because the presence of two tetramers is required to catalyse the destruction of a third one (**td**). The two individuals produced will then remain completely similar and only distinguishable from one another by their history.

As long as the environment remains atoxic and provides the required resources the autopoietic and self-reproduction processes never stop.

### Pathology

For some given values of the metabolic fluxes, the individual seems to remain in a basin of attraction. The measured lifespans of each of its components appear always in the same characteristic distribution. The histograms describing the distributions of their quantities are the same, and the correlations between are also unchanged. Of course, these observations are not a demonstration that this will always be the case.

Modifications of the flux of the metabolic pathways result in various morphological changes. Indeed, for each different metabolism a different shape results. Three examples of such morphologies are presented here (Figure 5) to demonstrate the diversity of the patterns that can be obtained. Reciprocally, modifications of the individual's shape can result in modifications of its metabolic fluxes.

The present set of regulations of Tiuccia enables always its total recovery. In some extreme cases, its metabolism can almost be stopped but no lysis or apoptosis phenomena can be observed. These phenomena constitute new properties and require the addition of new metabolic pathways to be attained.

### Description of "Lagny"

Lagny is a short chain of one-index particles each pointing towards the next. Only the last one points back towards the previous.

The whole looks like this:  $[>>>><]$ .

Let's call  $[><]$  the "head" and  $[>>>]$  the "tail".

The length of Lagny varies cyclically. Only three transitions are possible. During transitions (a) and (b), the head  $[><]$  "eats" a trimer  $[Y]$ . Trimers are rich in potential energy. "Eating" a trimer means releasing a dimer and keeping one unit of the trimer, which becomes a part of the head. Another part of the head is also transformed and lengthens the tail. The dimers  $[X]$  are poor in potential energy. Transition (c) releases a dimer from the end of the tail when it is long enough. The whole reaction set could be written as follows:

As each of its parts is continuously renewed by itself and it always keeps its cohesion, Lagny is an autopoietic individual.

Lagny can reproduce itself when it eats a dimer made of two two-link particles,  $[2-2]$ . This can happen only when its length is maximal. Once ingested, the  $[2-2]$  dimer transforms the beginning of the tail into a new head and settles between it, the one-unit tail, and the other head. The two heads continue eating as usual, and  $[2-2]$  serves as their link with each other and the tail. But, as the two new bodies keep growing,  $[2-2]$  is progressively pushed back towards the tail. Finally, when the two new bodies are long enough, the ancient tail completely disappears and a  $[2-2]$  dimer is expelled. This separates the two new similar Lagnys, which then continue independently.

As two identical shapes would have the same potential energy, nutrients, wastes and all their metabolic intermediates must have different shapes. These shapes are pure conventions and can be changed. Other components or transformations can be added. The following rules, however, must always be applied:

- If two components have different potential energy they must have different shapes.
- Each component of the individual must always be destroyed and renewed.
- Cohesion of the individual must always be ensured.

## Discussion

This model demonstrates that autopoiesis and self-reproduction are not only compatible, but that in the case of budding, the first can facilitate the second. It also confirms that bottom-up models, that were first used to analyse complex biological objects by representing and defining some of their functions, can now be used to synthesise new objects associating several of these properties. Additionally, in this model, pathological morphologies can be observed when some metabolic pathways are disturbed. Finally, several individuals of different natures can be simultaneously represented interacting within the same environment. The abstract characteristics of this model allow not only biochemical but also robotic, nano-physical, or other interpretations.

### Comparison to Other Models of Self-reproduction

In other models of self-reproduction, the individuals produced are not exactly similar and they are not autopoietic (Hutton, 2007). In some, they are not clearly separated (Ono and Ikegami, 2000). Some require the association of two different formalisms to represent movements and transformations (Smith et al., 2002) or small and large objects (Wishart et al., 2005). Others, partly because they use CA<sup>4</sup>, are neither autopoietic nor mobile (von Neumann, 1966; Langton, 1986; Sipper, 1998; Ishida, 2010). They invade space only during reproduction and then stay immobile. Some, like in molecular dynamic studies, are oriented towards the detailed description of a mechanism more than towards the integration of all of them to produce a biological property (Bersini, 2010). Swarm chemistries (Sayama, 2009) or diffusion–reaction models (Virgo et al., 2013) conform to some thermodynamic constraints but the “individuals” or their components do not have defined boundaries and anatomy. By contrast with agent based models, this formalism doesn't associate several functions to one object but several objects or parts of objects to one function. Functions are therefore described only once.

### Autopoiesis and Self-reproduction: Which Came First?

This model supports the hypothesis that, in the case of a budding mechanism (as opposed to division), a single structure could be sufficient to perform all of the mechanisms required for adding self-reproduction to autopoiesis. This structure would be synthesised when the individual's state indicates that it is healthy enough to reproduce itself. It would be able to separate and maintain linked a part of the membrane from the initial individual. When the inflow in the parent individual is sufficient, it would favour the use of a part of it to increase the size of this new membrane. As soon as this membrane has grown enough to perform its own entries itself, the autopoietic

regulations take over. Since the membrane is the energy entry point, the processes (metabolism and its regulation) that depend on the energy source will be activated. All the autopoietic regulations successively add up until the offspring has acquired most characteristics of the parent. The acquisition of the last of these characteristics would signal the separation. The structure that initiated budding disappears. Parent and offspring are identical. New budding processes can begin.

Can this relationship between autopoiesis and self-reproduction help us to understand how they appeared? According to the Oparin-Haldane hypothesis (see Popa, 2004), let's consider the case of a simply persistent individual capable of giving rise to an autopoietic individual. The transition to autopoiesis may, for example, be the creation of an isolate of the same composition as the parent but whose components are organized differently. The parts of this isolate are now linked together while it is still able to renew itself. We do not know if such a transition is a rare or common event since it does not produce a self-reproducing individual and, therefore, does not leave any trace.

Knowing that a single component may be sufficient to initiate and complete the process of self-reproduction, we can imagine that such a component was included in an isolate during a transition towards autopoiesis. If such an event occurred, it immediately created a new individual endowed with three major biological properties: autopoiesis, self-reproduction, and the ability to evolve.

If these properties did not arise simultaneously, one of them was acquired during the evolution of the other. However, only autopoietic individuals can acquire and control their self-reproduction. Persistent entities can only split and merge. Therefore, this model supports the hypothesis that self-reproduction was acquired either simultaneously with or after autopoiesis.

### Autopoiesis and Tolerance

The ability of autopoietic individuals to evolve depends on the control they exert on themselves. On one hand, this control enables them to better resist environmental variations than objects that are only persistent. On the other hand, if total, it may be an obstacle to any subsequent change. To acquire the ability to differentiate themselves from their parents, autopoietic individuals must be able to interact with new components. This implies an ability to tolerate some unexpected entries that are not constitutive parts of the individual.

Such a tolerance can seldom be passive, but most, if not all, known biological individuals are endowed with several active tolerance mechanisms, for example, redundancy of metabolic pathways, use of degenerate coding, compartmentalization, and ability to actively eliminate non-self components. This is associated with permanent identification of their self through an unceasing destruction and reconstruction.

The diversification of the entries has several consequences: it enables them to extract food from a greater variety of sources, and it allows new interactions with unknown foreign components which—even if insufficient—is a condition to the acquisition of new metabolic pathways including those required for self-reproduction.

Tolerance should be a target for future models.

<sup>4</sup> Cellular automata, because their rules modify only one cell's state, are unable to represent the coherence of objects in movement and interaction. Furthermore, starting from a given initial state, they calculate a determined unique trajectory and cannot show other possible evolutions and make probabilistic predictions. They are therefore more suitable for the description of an history than for prediction of possible future events. They can hardly be used to know what range of initial states and what kind of laws would have produced a given final state.

## Compatibility with Physical Laws

The model presented here allows an association of an entropy to each state space or part of the space. This entropy can be calculated by systematically enumerating all the possible distributions of the objects this space contains (complexions). Because each individual remains in a quasi-stable state in a basin of attraction, it is postulated that its entropy remains constant. Because the content of the environment is modified (for example, two trimers are removed while three dimers are added) it is postulated that the entropy of this environment increases.

To represent the conservation of energy, we must be able to calculate a quantity that remains constant from one transition to another. This quantity is equal to the sum of kinetic and potential energies of all the objects. A potential energy, a speed and a mass can be arbitrarily assigned to each object. From these data it is possible to calculate how the objects' speeds changed during conversions between potential energy and kinetic energy. However, in an asynchronous model, the speeds of all objects cannot be changed simultaneously and approximations are required<sup>5</sup>. It must be noticed that, due to the use of intermediate states (see methods), these approximations do not modify the order in which the dependent reactions occur.

Until a better approximation of kinetic energy is achieved, the only available reliable rule is that two identical shapes have the same potential energy. Therefore, nutrients, wastes, and, more generally, all their metabolic intermediates must have different shapes.

## Domain of the Individual in its Configurations Space

Here, the analogy between the biological reality and the model is consistent enough to justify the word "pathology". In both cases, we can distinguish a normal situation from several pathological ones. In "healthy" situations, the individual can attain its maximal performance in extraction and use of energy from its environment. In pathological situations, something is missing or in excess and the global performance is reduced. Each situation associates some anatomic (morphological) and physiological (functioning) characteristics.

In the case of Tiuccia, it has been observed that its mean renewal was faster with particular adjustments in the efficiency of some metabolic pathways. As this study is not extensive, it remains possible that better performance can be achieved with other adjustments.

Each possible morphology is a spot in the configurations space of the individual. This configurations space is an abstract space whose number of dimensions is equal to the number of classes of components of the individual. The individual is always in one place of this space. It can be in some places but not others. The set of places where it can exist constitutes its domain.

This model enables a systematic study of an individual's domain. This domain can be described spot by spot. However, by analogy with what is known of other physical (but not yet biological) systems, there may be approximations that allow more simple descriptions than

such an extensive enumeration. Such descriptions could rely on some characteristic parameters of the metabolism or associations of them. Some invariants might also be characteristic of the domain of each individual.

Another representation equivalent to the configurations space could be a transformations space whose number of dimensions would be equal to the number of transformations, each transformations varying in intensity.

## Towards a Systematic Enumeration of All the Life-as-It-Could-Be Forms?

It can be hypothesised that the domain description provides the most complete and simple representation of an individual as it comprises all its various metabolic states and the associated morphologies.

Domains descriptions could provide a method to distinguish an individual from one another. Given a set of constituents in a defined state and a set of relations between them, it should also be possible to know if they can constitute an individual or not.

These descriptions could also show how each individual is linked to its "relatives" and, therefore, open the way to a method allowing a systematic enumeration and classification of all the life-as-it-could-be forms (see Langton, 1986).

Finally, these questions are linked with epistemology since it can be hypothesized that, altogether, the description of all those life-as-it-could-be forms could constitute a Logical Tree of Life, independent of the Historical Tree of Life. All the statistical knowledge concerning reproducible biological phenomena should go in the first one; all the deterministic non-reproducible in the second.

## Conclusion

This model shows that, at least in the case of budding, autopoiesis facilitates self-reproduction. It analyses autopoiesis as an association of persistence plus cohesion and offers a rational definition of individuality. It supports the hypothesis that autopoiesis is simultaneous or precedes self-reproduction. It may be a guide towards a method allowing a systematic enumeration of all the life-as-it-could-be forms. It investigates the difficulties in representation of physical constraints and proposes some empirical rules.

The new platform used for these representations is a graph rewriting system embedded into a spatial automaton. It provides a simple and powerful language using combinations of a unique symbol to represent phenomena characterized by an unlimited variety of forms and interactions.

Graduate School for Information Science, Nagoya University, Japan  
solvi@alife.cs.is.nagoya-u.ac.jp

## Abstract

This paper describes an Artificial Life approach to Theory of Mind (ToM), the ability to employ mental representations of other minds in order to understand or anticipate the behaviour of others. We designed a model in which a population of neural network (NN) agents evolve the ability to predict, on basis of observation of past behaviour, others' future behaviour in novel circumstances. As agent behaviour is guided by private mental states, invisible to the predicting agent, this task forces agents to go beyond imitation and repetition of fit responses, requiring them to gain some degree of *insight* into the partner agent's internal configuration by observation of their externally visible behaviour. As such, this learning ability cannot be captured with conventional learning algorithms based on rewards or examples. We find that NNs equipped with neuromodulation mechanisms can be evolved to perform favourably on this task. The resulting networks are seen to behave as though they have a primitive form of first order ToM.

## Introduction

Theory of Mind (ToM) is the ability to employ mental models (representations) of other minds, in order to understand or anticipate the behaviour of others (Premack and Woodruff, 1978). The adaptive advantages of ToM are likely to be a driving factor in the evolution of cognition that recognizes others as well as itself as intentional agents. While ToM has become a hot topic in cognitive psychology and related fields, the phenomenon of "mirror neurons" (neurons that activate both when a given action is performed and when the same action is observed) has become a hot topic in cognitive neuroscience. Many researchers are intuitively inclined to link these two phenomena, thinking of mirror neurons as a neural basis for ToM, but the relation between the two remains murky. As such it seems potentially informative to try and evolve ToM-like abilities in neural systems.

Representation is a tough issue in connectionist AI, but mental representation of other minds presents a special challenge in at least two aspects: (1) Other minds are themselves capable of representing, leading to recursive and reflexive scenarios such as mind X representing a mind Y that itself represents mind X (see also Dennett, 1987). This point in particular complicates the connection with mirror neurons, which so far have not been observed to engage in recursive mirroring (although some have theorized about recursive functionality, see Gallese, 2007). (2) Other minds are invisible: we cannot see the minds of others, we can only guess at the existence of other minds via observation of behaviour. This point has di-

rect implications for learning about other minds: One might learn about another's behaviour via direct observation of that behaviour, but for learning about another's mind one needs forms of learning ability that incorporate inference from externally visible behaviour to (invisible) mental states. This sort of learning is difficult to capture with traditional AI conceptualizations of learning. Indeed, while computational work on ToM exists, the mechanisms for representing other minds are usually explicitly given and fixed (see e.g. Takano and Arita, 2006; Noble et al., 2010) (placing the focus on recursion depth instead). In this research we instead aim to let such mechanisms evolve from scratch, using a minimalistic evolutionary neural network model.

## Model

Agents are implemented as neural networks (NNs). Network architecture is evolved using a basic Genetic Algorithm. Agents interact in pairs. During its lifetime, each agent is part of multiple pairings. In each pair, there is a fixed role division: one agent acts at zero-order ToM ( $L_0$ ), meaning it ignores the other agent and simply reacts on basis of the state of the environment and its own mental state, and the other agent acts at first-order ToM ( $L_1$ ), meaning it tries to anticipate the behaviour of the  $L_0$  agent (at present, the  $L_1$  agent is simply tasked with predicting the  $L_0$  agent's behaviour). Each pair interacts for a set number of time-steps.

Our model is not intended to capture any specific social interaction scenario in particular. Instead we take a more abstract approach, in which the logic that determines the fitness payoff for performing a given action in a given state is generated randomly for each experiment (i.e. the fitness function is randomly generated for each run of the model). The idea is that if arbitrary fitness functions can be handled successfully, then the model has generality. Thus there is no concrete "task" to solve, there are merely *environmental states*, *mental states*, *actions*, and a randomly generated *base logic* that relates these elements.

*Environmental state*: bit-string of length  $N_e$  (set to 3 in the experiments discussed in this paper). The environmental state is shared between interacting agents (i.e. both agents see the same state). The environmental state changes every time-step. Each pair of agents sees each environmental state exactly once, in random order.

**Mental state:** bit-string of length  $N_m$  (set to 3 in the experiments discussed in this paper). Each agent has a private mental state, invisible to its interaction partner. Mental states remain constant over the course of the interaction of an agent pair.

**Action:** bit-string of length  $N_a$  (set to 3 in the experiments discussed in this paper). At each time-step, each agent outputs an action.

**Base logic:** generates the optimal  $L_0$  action choice for each (environmental state, mental state) pair. The base logic abstractly represents social scenarios. The base logic is implemented as a neural network, identical in kind to the NNs used for the agents, although with a few restrictions (we detail the way the base logic is generated after we explain the agent NN architecture below).

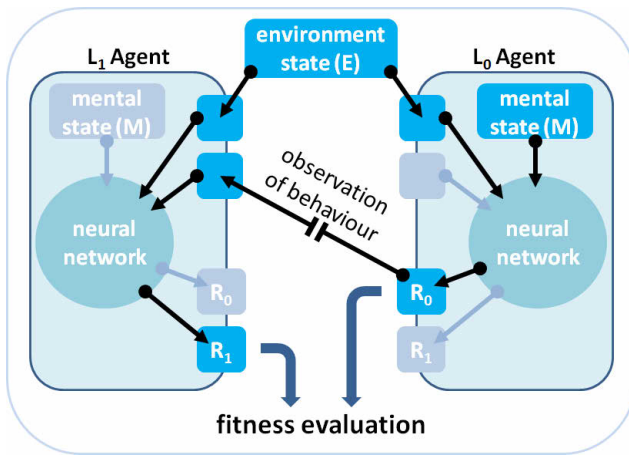

Figure 1. Schematic of agent interaction. The  $L_0$  agent computes its action ( $R_0$ ) from the (shared) environmental state and its (private) mental state. The  $L_1$  agent computes a prediction ( $R_1$ ) of this action. After the prediction is made,  $R_0$  is revealed to the  $L_1$  agent as data to drive its learning process.

Fitness scores for the action choices of the agent performing the  $L_0$  role are calculated as proximity to the optimal action as generated by the base logic, normalized to the  $[-1, +1]$  interval. Meanwhile, fitness scores for the action choices of the agent performing the  $L_1$  role are calculated as proximity to the action choice of the  $L_0$  agent. As such, the  $L_1$  agent must try to predict the action of the  $L_0$  agent, but the action choice of the  $L_0$  agent depends on the  $L_0$  agent's mental state, which is invisible to the  $L_1$  agent. Herein lies the challenge: in order for the  $L_1$  agent to be able to predict the  $L_0$  agent's future moves under future environmental states, the  $L_1$  agent must infer the  $L_0$  agent's mental state from the  $L_0$  agent's action choices under the current and preceding environmental states. By observing both the  $L_0$  agent's action choice and the environmental state that led the  $L_0$  agent to choose that action, the  $L_1$  agent has the necessary information to infer the  $L_0$  agent's mental state, and on the basis thereof it can predict the  $L_0$  agent's behaviour under other environmental states.

## Network species

We use a slightly unusual type of NN, which gives a central position to propagation order. A network consists of a list of neurons and a set of connections. Propagation simply follows the list order. The genome encodes for each connection the list-indices of the pre-synaptic neuron and the post-synaptic neuron. If the index of the post-synaptic neuron is smaller (or equal) to the index of the pre-synaptic neuron, then the connection runs against the propagation direction and is thus treated as a recurrent connection (meaning activation sent over it arrives at the next time-step). Otherwise, it runs along the propagation direction and is treated as a regular connection (meaning activation sent over it arrives at the same time-step). This approach avoids the trouble of deriving propagation order in free-form evolvable NN architectures, and facilitates later implementation of endogenously controlled propagation loops for recursive ToM.

The neuron list is composed of seven sections:  $2 \cdot N_m$  neurons for mental state input,  $2 \cdot N_e$  neurons for environmental state input,  $2 \cdot N_a$  neurons for partner action input,  $H$  hidden neurons,  $N_a$  neurons for  $L_0$  action output, again  $H$  hidden neurons, and finally  $N_a$  neurons for  $L_1$  action output. Connections between two neurons inside one and the same input or output section are not allowed. We provide two neurons for each input bit. Activation of one neuron signals a 1 value and activation of the other neuron signals a 0 value for the bit. These values can have very different implications, so we input them separately. When a NN acts as  $L_0$ , its responses are read from the first set of output neurons, and when it acts as  $L_1$ , the second set is read. When reading out responses at the output neurons, we translate neural activation values into binary values by converting negative values into zeroes and positive values into ones. Figure 2 shows the basic architecture (for  $N_m = N_e = N_a = 1$  and  $H = 2$ ). In the experiments discussed in this paper we used the following settings:  $N_m = N_e = N_a = 3$  and  $H = 16$ , making for a total of 56 neurons. Given that connectivity is evolved, it is very well possible for neurons to not be included in the circuitry, meaning that the "effective" net size will generally be smaller than 56. The maximum number of connections is limited to 100.

A neuron's activation is computed from the activation of the neurons that project to it, using a slight modification of the standard hyperbolic tangent activation function.

Activation function:

$$A_j = N_j \cdot \tanh \left[ 0.5 \cdot \sum (W_{ij}^A \cdot A_i) \right] + b_j$$

Where  $A_i$  is activation at neuron  $i$ ,  $W_{ij}^A$  is the weight of an activatory connection from  $i$  to  $j$ ,  $b_j$  is the (genetically encoded) activation bias for neuron  $j$ , and  $N_j$  is the neurotransmitter value at neuron  $j$ .  $N_j$  defaults to 1, but can be lowered if the neuron has any incoming *neurotransmitter connections*. Activation received over such connections is added to the  $N_j$  value.  $N_j$  is clipped to the  $[0, 1]$  range before the activation function is applied, and reset to 1 after propagation. This neurotransmitter logic is included to provide a simple mechanism for blocking signal transmission, which can simplify some neural computations (e.g. xor without hidden neurons). While theoretically speaking this does not expand the functionality

of the network species, we do find inclusion of such a neurotransmitter system to improve evolvability.

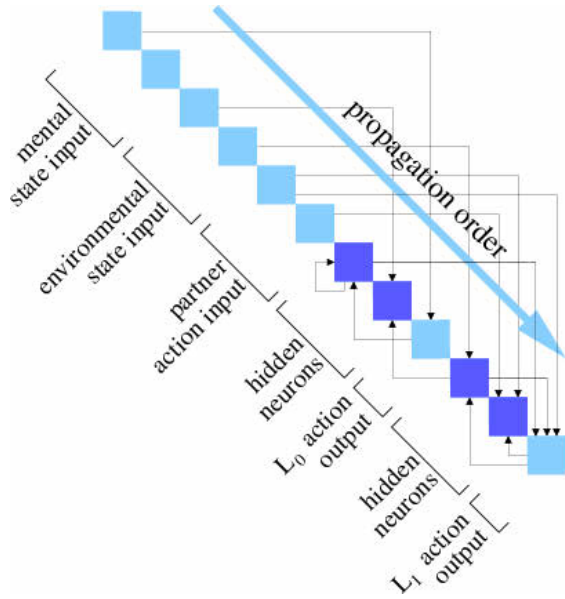

Figure 2. Neural network architecture concept. Networks consist of seven sections, with the size of each section determined by model parameters (see text). Propagation order is fixed. Connections running against the propagation order are treated as recurrent connections.

Evolution of learning ability is made possible using neuromodulation (Soltoggio et al., 2008). Similar techniques have previously been employed to evolve spatial representation ability in NNs (Arnold et al., 2012, 2013), so it stands to reason that it might allow for evolution of social representation ability as well. The basic idea is to introduce a special connection type that lets neurons send modulatory signals to one another, and to let these signals control connection weight change. This allows for evolution to shape the weight update dynamics of the networks by shaping the modulatory connectivity, which provides a basis for endogenously controlled behaviour change, i.e. a basis for learning ability. So in addition to their activation value, neurons have a modulation value, and in addition to standard activatory connections, there are modulatory connections. If neuron  $i$  has a modulatory connection to neuron  $j$ , then activation at  $i$  leads to modulation at  $j$ . Neurons' modulation values are computed in similar fashion to their activation values, but without involvement of neurotransmitter values.

Neuromodulation function:

$$M_j = \tanh \left[ 0.5 \cdot \sum (W_{ij}^M \cdot A_i) \right]$$

Where  $M_i$  is modulation at neuron  $i$ , and  $W_{ij}^M$  is the weight of a modulatory connection from  $i$  to  $j$ .

Weight updates are computed from the activation and modulation values at the pre- and post-synaptic neurons as follows:

$$\Delta W_{ij} = A_i^{g_{ij}^0} \cdot A_j^{g_{ij}^1} \cdot M_i^{g_{ij}^2} \cdot M_j^{g_{ij}^3}$$

Where  $\Delta W_{ij}$  is the change in the weight of the connection from neuron  $i$  to neuron  $j$ , and  $g_{ij}^0 \dots 3$  are binary genes that encode inclusion/exclusion of each term in the update function for this specific connection. Connection weights are clipped to  $[-1, +1]$ .

Weight updates are only performed when the network plays the role of an  $L_1$  agent (the behaviour target for  $L_0$  agents is static, so no learning is required there). When an agent plays the  $L_1$  role, propagation is performed twice. The first time, only the environmental state is given on the input neurons, propagation is performed, and the action prediction is read out on the  $L_1$  output neurons. Then the environmental state and the actual action choice of the  $L_0$  agent are given as input, propagation is performed, and connection weights are updated. In the second propagation round, output is ignored.

## Genetic Algorithm

Networks are evolved using a Genetic Algorithm, with mutation but no crossover. After each generation, agents are sorted by fitness, after which the worst performing two thirds of the population is replaced with copies of the best performing one third, to which then mutation is applied. Mutations can alter the following properties:

### Connections

- Pre- and post-synaptic neuron indices
- Type (activatory, neurotransmitter, modulatory)
- Update rule genes ( $g_{ij}^0 \dots 3$ )
- Existence

### Neurons

- Activation bias value

The "existence" property is used for addition and removal of connections (technically speaking there are always 100 connections in the network, but those with the existence property set to false are skipped over when the propagation logic is performed).

We additionally include some special mutation operators for modifying neural pathways, such as "inserting" a neuron into a pathway (given a connection from neuron  $x$  to neuron  $z$ , this operator picks a random neuron  $y$  and then replaces the original  $xz$  connection with a  $xy$  and a  $yz$  connection), and "removing" a neuron from a pathway (given a neuron  $y$ , it finds a connection projecting from some  $x$  to  $y$  and a connection from  $y$  to some  $z$ , and replaces the  $xy$  and  $yz$  connections with a single  $xz$  connection). Necessity of such operators has not been investigated here.

When mutating a network, we first pick a mutation rate using the following rule:

$$\begin{aligned} \text{rate} &= 16 \cdot R(0,1)^6 \\ \text{rate}_{\text{neuron}} &= \text{rate} / \text{neurons} \\ \text{rate}_{\text{connection}} &= \text{rate} / \text{connections} \end{aligned}$$

Where  $R(0,1)$  generates random numbers in the interval  $[0,1]$ , *neurons* is the number of neurons in the agent networks (56 in our experiments), and *connections* is the maximum number of connections in the agent networks (100 in our experiments). The resulting  $\text{rate}_{\text{neuron}}$  and  $\text{rate}_{\text{connection}}$  values are then used as the mutation probabilities per neuron and per connection, respectively. This slightly convoluted system for computing mutation rates is intended to help evolution by producing a good mixture of heavily and mildly mutated individuals, and was found to work better than fixed mutation rates.

### Generating the base logic

As noted above, we use random base logics instead of specific social scenarios. Base logics are implemented as special instances of the neural network architecture described above, and generated using the same genetic algorithm, just using a different fitness function than used when evolving agent NNs. The base logic serves as the target phenotype for  $L_0$  agents (i.e. fitness of  $L_0$  behaviour is judged as proximity to the base logic). As the base logic is just a special exemplar of the same neural network species, it takes environmental and mental states as input and returns actions as output. The fitness function used for generating base logics assesses the suitability of this input-output mapping as a social task, using the product of two values:

*Environmental state relevance*: for each possible mental state, we count the number of different action outputs that can be obtained by varying the environmental state. This gives an indication of the relevance of the environmental state for optimal action choice. If different environmental states do not lead to different optimal actions, then little can be learned by observing another agent in different environmental states. Thus the base logic should have a high value for environmental state relevance, to make learning *possible*.

*Mental state relevance*: for each possible environmental state, we count the number of different action outputs that can be obtained by varying the mental state. This gives an indication of the relevance of the mental state for optimal action choice. If different mental states do not lead to different optimal actions, then there is no need for  $L_1$  agents to learn about the mental state of the  $L_0$  agent. Thus the base logic should have a high value for mental state relevance as well, to make learning *necessary*.

Expressed in formulaic form:

$$\text{fitness}_{\text{logic}} = \sum_{\text{mst}}^{\text{m}} \text{actions}(\text{m}) \cdot \sum_{\text{env}}^{\text{e}} \text{actions}(\text{e})$$

Where *mst* is the set of possible mental states, *env* is the set of environmental states,  $\text{actions}(\text{m})$  is the number of distinct actions that can be obtained for mental state *m* by varying the environmental state, and  $\text{actions}(\text{e})$  is the number of distinct actions that can be obtained for environmental state *e* by varying the mental state.

While we use the same network architecture, some limitations are imposed when a network is used as base logic. First off, the base logic should remain constant over time-steps, so modulatory and recurrent connections are disabled. Secondly, the base logic only provides the optimal actions for  $L_0$  (for  $L_1$ , optimal action is imitation of  $L_0$ ), so neurons beyond the first

output section are omitted. Thirdly, to ensure that agents can viably replicate the base logic phenotype, we limit the number of neurons in the hidden neuron section to half of that used in the agent networks (i.e. 8 instead of 16).

We evolve a base logic population of 225 networks for 2000 generations, and retain the best individual of the final generation as the base logic for the experiment. Then a population of 225 agent networks is evolved for 2,000,000 generations.

### Evolving the agent population

In each generation, we split the population into 25 groups of 9 agents each. Within each group, every possible agent pairing interacts twice (once for each role assignment). At the start of each interaction, the  $L_0$  agent generates a mental state, which remains constant throughout the interaction. Then the  $L_0$  agent is exposed to every possible environmental state, in random order, while the  $L_1$  agent tries to predict the  $L_0$  agent's actions, seeing the shared environmental state but not the  $L_0$  agent's mental state. After each action of the  $L_0$  agent, the actual action choice is revealed to the  $L_1$  agent (i.e. fed into its "partner action" input neurons), and weight update logic is performed. Each environmental state is seen only once per interaction, so simply remembering the partner's action choice is no viable strategy. For the  $L_0$  agent, fitness payoff for an action is simply proportional to the action's proximity to the optimal action as given by the base logic. Below we use the performance of the  $L_1$  agent on the last time-step of the interaction as a measure of the success of the learning process. However,  $L_1$  fitness as used by the genetic algorithm is measured over all steps, so that a faster learner will have better fitness than a slow learner even if they perform equally well on the last time-step of the interaction.

At the end of each generation, agents are ranked per group, on basis of their  $L_0$  performance and  $L_1$  performance, with  $L_0$  performance taking precedence over  $L_1$  performance. That is, if agent *X* has a higher  $L_0$  performance than agent *Y*, then *X* will be ranked above *Y*, independent of the  $L_1$  performance scores. When *X* and *Y* have identical  $L_0$  scores (a very common occurrence, especially once optimality on the  $L_0$  task has been achieved), rank is decided by the  $L_1$  score. This way of ranking avoids a trap in social evolution. If evolution co-opts the neural circuitry that determines  $L_0$  behaviour for prediction of other agents'  $L_0$  behaviour (i.e.  $L_1$  behaviour), then when a mutant with better circuitry for  $L_0$  behaviour appears, this mutant will have *worse* prediction ability with respect to the behaviour of its non-mutant peers (and those peers will have worse prediction ability with respect to the mutant). To prevent such effects from obstructing evolution of  $L_0$  behaviour,  $L_0$  performance should take precedence of  $L_1$  behaviour. The best one third of each group (3 agents with the settings used here) overwrites the remaining two thirds with copies of themselves (so 2 copies per agent), to which mutation is applied. So effectively the parent agents each have 3 offspring, 2 mutated and 1 unmutated.

## Results

Eight trials of the experiment described above were performed. Table 1 shows performance results for the final 1000 generations of each trial, and Figure 3 shows the evolution

process of a representative run. The scores displayed for  $L_0$  are computed over individuals that have been retained without mutation from the previous generation (i.e. the unmutated offspring of the previous generation). Note that this implies that inclusion of an individual in the performance score is decided *before* its performance is measured. Such scores provide a good performance measure, as they are neither distorted much by mutation (as whole population averages are) nor by luck (as population best scores are). Scores displayed for  $L_1$  are computed over all pairings between such individuals.

Run #	Max $L_1$ score without learning	$L_0$ score	$L_1$ score
1	.21	.9195	.9841
2	0	.9984	.9062
3	.20	.9861	.9641
4	.05	.9506	.8972
5	.34	.9199	.9745
6	0	.9961	.9690
7	.21	.9995	.9941
8	.29	.8839	.8974
average	.1625	.9568	.9483

Table 1. Performance scores. Scores are averages over the last 1000 generations of each run. Score averages for  $L_0$  are taken over all individuals that have been copied from the previous generation without mutation. Score averages for  $L_1$  are taken over all pairings between such individuals.

Variation in partner  $L_0$  behaviour will harm  $L_1$  performance of even optimal agents. As such, perfect performance cannot be expected. To allow for assessment of the evolved learning ability, we calculated the maximal expected fitness score agents without learning could obtain for each run's base logic, and show these alongside the performance scores in Table 1. These are the expected  $L_1$  scores achieved by a hypothetical non-learning agent that for each environmental state simply picks the action that (over all possible mental states for an optimal  $L_0$  partner agent) yields the best expected score. Note that the expected score for random behaviour is 0. We can see that  $L_1$  performance in all runs widely exceeds the computed maxima for non-learning agents, showing that learning ability was indeed evolved. Average performance over all runs is well over 90% of the theoretical maximum, and some runs get very close to maximum performance (runs 3, 6 & 7).

These results indicate that the model, while far from perfect, is capable of producing agents that can learn how their interaction partner maps environmental states to actions. In that mapping, the partner's mental state plays a central role. As such, it seems that by observing their partner's behaviour, the agents in some form or another get a grasp on their partner's

mental state. This suggests that these agents have evolved a primitive form of first-order Theory of Mind.

Figure 3. Evolution process of example run (run 4 in Table 1). As in Table 1,  $L_0$  scores are averages over unmutated individuals and  $L_1$  scores are averages over interactions between such individuals. Data points are smoothed over 100 generations. X-axis in log-scale. Initially the population adopted a simple  $L_0$  behaviour, easy to imitate (hence high  $L_1$  scores early on) but low in fitness. As the  $L_0$  behaviour improves we see the  $L_1$  performance fall, and then climb back up again as the learning ability necessary for prediction of the more complex  $L_0$  behaviour evolves. Eventually the system settles in a state with high performance for both  $L_0$  and  $L_1$ .

## Future Work

The networks evolved here act as though they have first order ToM, but we have yet to establish how the mental state of partner agents is represented in the networks' activation patterns and/or weight modifications. Our primary future goal is to investigate this. It is well known that more often than not, networks evolved or trained to solve a given task represent their knowledge in highly diffuse and distributed fashion. However, as we have shown elsewhere (Arnold et al., 2012, 2013), when evolution and learning are combined, interactions between them tend to give rise to more organized forms of representation. In the present work too, we have a combination of learning and evolution at work.

Secondly, specific to ToM, we will investigate whether, in predicting an  $L_0$  partner's behaviour, these nets use the circuitry they use when they themselves are performing at  $L_0$ . This would constitute a mirror-neuron-like, "placing oneself in another's shoes" approach to the problem.

Beyond the above, we aim to extend this research in the following directions: 1) More complex scenarios for the  $L_1$  response (i.e. not mere prediction, but acting in anticipation of the  $L_0$  agent's action). 2) Extension to higher (recursive) orders of ToM (by introducing endogenously controlled propagation looping in the NN architecture). 3) Once the model works for mental and environmental states of sufficient size, replacement of the randomly generated base logic with simple games or cognitive psychology experiments that involve ToM.

## Abstract

In this paper, a hardware platform for coevolutionary cartesian genetic programming is proposed. The proposed two-population coevolutionary algorithm involves the implementation of search algorithms in two MicroBlaze soft processors (one for each population) interconnected by the AXI bus in Xilinx Virtex 6 FPGA. Candidate programs are evaluated in a domain-specific virtual reconfigurable circuit incorporated into custom MicroBlaze peripheral. Experimental results in the task of evolutionary image filter design show that we can achieve significant speed-up (up to 58) in comparison with highly optimized software implementation.

## Introduction

Cartesian genetic programming (CGP) – a special variant of genetic programming (GP) – has been successfully applied to a number of challenging real-world problem domains (Miller, 2011). However, the computational power that evolutionary design based on CGP (as well as on standard GP) needs for obtaining innovative results is enormous for most applications. Often, the fitness in GP is calculated over a set of *fitness cases* (Vanneschi and Poli, 2012). A fitness case corresponds to a representative situation in which the ability of a program to solve a problem can be evaluated. Fitness case consists of potential program inputs and target values expected from a perfect solution as a response for these program inputs.

A set of fitness cases is typically a small sample of the entire domain space. The choice of how many fitness cases (and which ones) to use is often crucial since whether or not an evolved solution will generalize over the entire domain depends on this choice. However, in the case of digital circuit evolution, it is necessary to verify whether a candidate  $n$ -input circuit generates correct responses for all possible fitness cases (input combinations, i.e.  $2^n$  assignments). It was shown that testing just a subset of  $2^n$  fitness cases does not lead to correctly working circuits (Imamura et al., 2000). Recent work has indicated that this problem can partially be eliminated in real-world applications by applying formal verification techniques (Vasicek and Sekanina, 2011).

Hillis (1990) introduced an approach that can automatically evolve subsets of fitness cases concurrently with problem solution. Hillis used a two-population coevolutionary algorithm (CoEA) applied to a test-based problem in the task of minimal sorting network design. Subsets of test cases used to evaluate sorting networks evolved simultaneously with the sorting networks. Evolved sorting networks were used to evaluate the test cases subsets. The fitness of each sorting network was measured by its ability to correctly solve fitness cases while the fitness of the fitness cases subsets was better for those that could not be solved well by currently evolved sorting networks.

Coevolutionary algorithms are traditionally used to evolve interactive behavior which is difficult to evolve with an absolute fitness function. The state of the art of coevolutionary algorithms has recently been summarized in (Popovici et al., 2012). A *test-based problem* is defined as a co-search or co-optimization problem with two populations – population of candidate solutions and population of *tests* (subsets of the fitness cases set).

In our previous work, inspired by *coevolution of fitness predictors* (Schmidt and Lipson, 2008) and the principles of the *competitive coevolution* introduced by Hillis (1990), we proposed a two-population coevolutionary CGP algorithm running on an ordinary processor in order to accelerate the task of symbolic regression (Šikulová and Sekanina, 2012b) and the evolutionary image filter design (Šikulová and Sekanina, 2012a). For our benchmark problems (5 symbolic regression problems and salt-and-pepper noise filter design) we have shown that the (median) execution time can be reduced 2-5 times in comparison with the standard CGP.

Despite the acceleration based on fitness cases coevolution, the CGP design is still computationally very intensive design method. Therefore an FPGA based acceleration platform has been designed. Modern FPGAs provide cheap, flexible and powerful platform, often outperforming common workstations or even clusters of workstations in particular applications. Vasicek and Sekanina (2010) introduced a new FPGA accelerator of CGP with the aim to provide both high performance and low power. The architecture

contains multiple instances of *virtual reconfigurable circuit* (VRC, Sekanina (2003)) to evaluate several candidate solutions in parallel.

Inspired by the FPGA accelerator of CGP, we propose a hardware platform for parallel two-population CoEA and show that by using this platform, the execution time of evolutionary design using CGP can be significantly reduced. The proposed hardware accelerated coevolutionary CGP is compared with hardware-accelerated standard CGP and with a highly optimized software implementation of coevolutionary CGP in the task of evolutionary image filter design.

The paper is organized as follows. The next section introduces the idea of coevolution in cartesian genetic programming. In the following section the architecture of the proposed accelerator is presented. The remaining section is devoted to experimental evaluation of the accelerator in the benchmark problem – the image filter evolution. Conclusions are given in the last section.

### Coevolution in Cartesian Genetic Programming

In standard CGP (Miller, 2011), a candidate program is represented in the form of directed acyclic graph, which is modelled as an array of  $n_c \times n_r$  (columns  $\times$  rows) programmable elements (nodes). The number of primary inputs,  $n_i$ , and outputs,  $n_o$ , of the program is defined for a particular task. Each node input can be connected either to the output of a node placed in previous  $l$  columns or to one

of the program inputs. The  $l$ -back parameter, in fact, defines the level of connectivity and thus reduces/extends the search space. Feedback is not allowed. Each node is programmed to perform one of  $n_a$ -input functions defined in the set  $\Gamma$ . Each node is encoded using  $n_a + 1$  integers where values  $1 \dots n_a$  are the indexes of the input connections and the last value is the function code. Every individual is encoded using  $n_c \cdot n_r \cdot (n_a + 1) + n_o$  integers.

A simple  $(1+\lambda)$  evolutionary algorithm is used as a search mechanism. It means that CGP operates with the population of  $1 + \lambda$  individuals (typically,  $\lambda$  is between 1 and 20). The initial population is constructed either randomly or by a heuristic procedure. Every new population consists of the best individual of the previous population (so-called parent) and its  $\lambda$  offspring. In each generation, an offspring with equal or better fitness than the parent's is chosen as the new parent. The offspring individuals are created using a point mutation operator which modifies up to  $h$  randomly selected genes of the chromosome, where  $h$  is a user-defined value. The algorithm is terminated when the maximum number of generations is exhausted or a sufficiently working solution is obtained.

There are two concurrently evolving populations in the proposed coevolutionary algorithm: (1) candidate programs evolving using CGP and (2) tests (*fitness cases subsets*, *abb. FCSs*) evolving using a simple genetic algorithm. Both populations evolve simultaneously and interact through the fitness function.

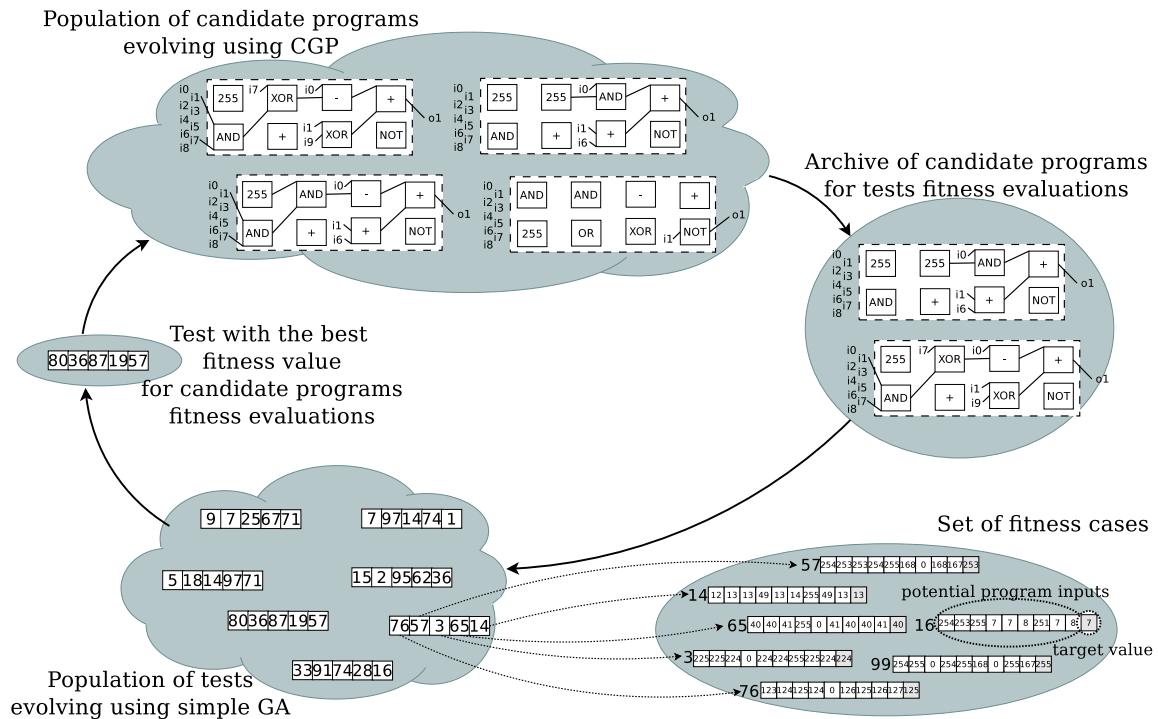

Figure 1: Populations in coevolutionary CGP – candidate programs and tests.

Test is a subset of the fitness cases set, therefore every test is encoded as a fixed-sized array of pointers to elements in the fitness cases set. In addition to one-point crossover and mutation, a randomly generated tests replacing the worst-scored tests in each generation has been used.

The aim of coevolving tests and candidate programs is to allow both candidate programs and tests to enhance each other automatically until a satisfactory problem solution has been found. Figure 1 shows the overall scheme of the proposed method. If the top-ranked candidate program fitness value (in the actual generation of candidate programs evolution) has changed against the previous generation, the top-ranked candidate program is copied to the archive of candidate programs. The archive of candidate programs is a circular list that is used for tests evaluation. Tests (in the tests evolution) are evaluated using candidate programs from the archive as follows. Each candidate program from the archive is executed for all fitness cases in the test. The test with the worst mean fitness value for candidate programs from the archive is selected as the top-ranked test in the actual generation. This test is then used to evaluate candidate programs in the candidate programs evolution. This fitness interaction approach allows to improve candidate programs using the fitness cases, which cannot be correctly solved by currently evolved candidate programs yet.

### Hardware platform design

The evolutionary design includes two basic steps alternating in each generation – generation of new population and evaluation. Since the evaluation step consists in multiple running or simulating of candidate program and computing chosen fitness, a significant acceleration can be achieved by means of task or data parallelism, while the best throughput can be achieved using custom hardware.

On the contrary, the evolutionary process control is, by its nature, suitable rather for running on a universal processor, moreover in the case of CoEAs two evolutionary processes need to be executed in parallel with the ability to communicate with each other.

These requirements have been taken into account when choosing the target platform. Currently, two suitable alternatives are available – conventional FPGAs and a combination of a processor and programmable logic (e.g. Xilinx Zynq All Programmable SoC, Dobai and Sekanina (2013)). Table 1 compares several devices available in our institution as part of a development kit with respect to the configurable logic

Table 1: Target platforms comparison.

	device	logic cells	block RAM
	Virtex 6 XC6VLX240T	241,152	14,976 Kb
	Virtex 7 XC7K325T	326,080	16,020 Kb
	Zynq 7020 XC7Z020	85,000	4,480 Kb

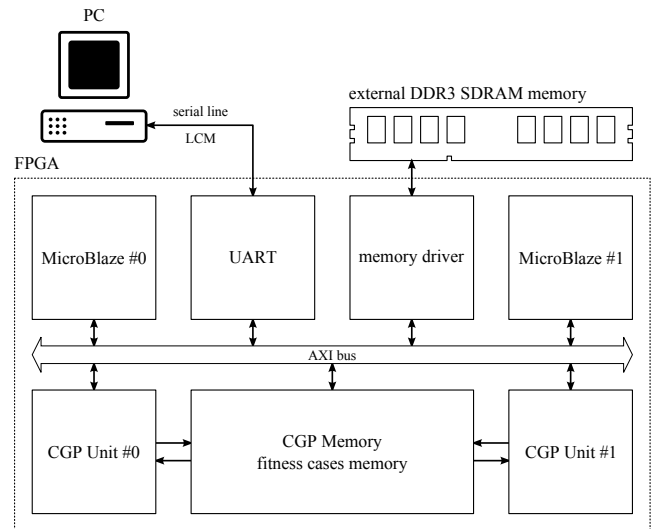

Figure 2: Hardware platform architecture.

cells count and the amount of block RAM. It is obvious, that the Zynq platform offers much less flexibility in terms of custom logic comparing to Virtex FPGA family. Therefore, a standard FPGA has been chosen as a more flexible option.

Despite the fact that standard FPGAs do not have hard processors, wide choice of soft processors under various licences are available. The most suitable choice for Xilinx devices is the MicroBlaze soft processor, offering sufficient performance while occupying a reasonable area. Figure 2 shows the proposed hardware platform architecture. The system consists of two MicroBlaze soft processors supplemented by two independent acceleration units (CGP Units) and fitness cases memory (CGP Memory). All components are interconnected by the AXI bus and additional memory channels are introduced for fitness cases transfers. Com-

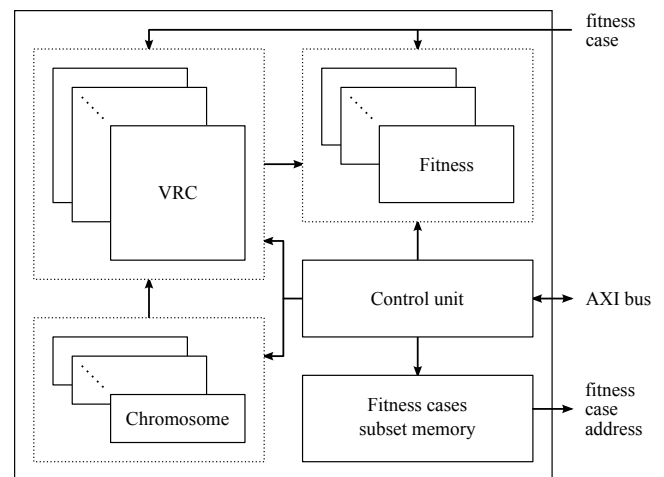

Figure 3: Detailed architecture of CGP Unit.

Figure 4: Virtual Reconfigurable Circuit (VRC).

munication with a service application running on a PC is performed through serial port (UART) and LCM communication library<sup>1</sup>. The dual MicroBlaze system utilizes AXI Mailbox component, which enables to pass simple messages between the processors (control and status messages, chromosomes, fitness values etc.).

CGP Unit (Figure 3) includes a set of subcomponents, each composed of one virtual reconfigurable circuit (VRC), fitness unit and chromosome register. Moreover, the CGP Unit includes a common control unit and FCS memory, each subcomponent is fed with the same data. The control unit is responsible for the communication between the MicroBlaze processor and the peripheral and for controlling the fitness computation. There are several configuration and status registers that are memory mapped on the AXI bus together with the test memory. By setting a specific bit in the control register, the fitness computation starts. Fitness cases are addressed indirectly using the test memory, which is addressed sequentially by the control unit. In the case of image filter design, each fitness case consists of chosen, e.g.  $3 \times 3$  or  $5 \times 5$ , pixel neighbourhood from the noisy image and one pixel from the original image. The noisy pixels are processed in the VRCs and together with the clean pixel, properly delayed, come to the fitness unit. After a specified number of fitness cases is processed, the control unit saves the current fitness values and notifies the MicroBlaze processor by changing the status register value.

The VRC architecture is shown in Figure 4. According to the program representation in CGP, the VRC comprises a grid of nodes, called configurable function blocks (CFBs), interconnected in such a way that each block can access all other blocks in previous columns and the VRC inputs. Both VRC's inputs and CFB's outputs are registered and delayed, so that the VRC is fully pipelined while keeping the  $l$ -back parameter of arbitrary choice. Thanks to the pipelining, the

<sup>1</sup>Lightweight Communications and Marshalling (LCM) is a set of libraries and tools for message passing and data marshalling originally designed by the MIT DARPA Urban Challenge Team.

Table 2: Functions implemented in CFBs according to Sekanina et al. (2011).

#	function	#	function
0	255	8	$i_1 \gg 1$
1	$\frac{i_1}{i_2}$	9	$i_1 \gg 2$
2	$\frac{i_2}{i_1}$	10	$(i_1 \ll 4) \vee (i_2 \gg 4)$
3	$\frac{i_1}{i_2} \vee i_2$	11	$i_1 + i_2$
4	$\frac{i_1}{i_2} \wedge i_2$	12	$i_1 +^s i_2$
5	$\frac{i_1}{i_2} \wedge i_2$	13	$(i_1 + i_2) \gg 1$
6	$\frac{i_1}{i_2} \wedge i_2$	14	$\max(i_1, i_2)$
7	$i_1 \oplus i_2$	15	$\min(i_1, i_2)$

VRC is able to process one fitness case per clock cycle.

Each CFB has the same structure. The input data are selected using two multiplexers and forwarded to several functions (functions used for image filter design are listed in Table 2), the output value is selected by an output multiplexer. The configuration of the multiplexers is determined by specific genes of the chromosome.

The output of each VRC is connected to separate fitness unit (Figure 7). Two different fitness functions are computed simultaneously – squared and absolute error:

$$f_{sq} = \sum_{i=1}^N (x_i - y_i)^2, \quad (1)$$

$$f_{abs} = \sum_{i=1}^N |x_i - y_i|,$$

where  $x_i$  is the clean pixel,  $y_i$  the VRC output corresponding to the  $i$ -th fitness case and  $N$  the number of fitness cases. These fitness functions are very similar to the MSE and MDPP functions (commonly used for image filter design), except for normalization with the number of pixels  $N$ . Since division is a very demanding operation, its removal saves a lot of resources without any impact on the application in EAs. While performing experiments, one can choose which

Figure 7: Fitness unit.

fitness function is used for the evaluation.

The CGP Memory component (Figure 8) is designed to achieve very high throughput. One write port (connected to the AXI bus) and two read ports enable to supply both CGP Units with data. These ports have different data widths because the AXI bus is 32 bit wide, but the width of the fitness case depends on the chosen pixel neighbourhood (80 bits for  $3 \times 3$ , 208 bits for  $5 \times 5$ ). Therefore the memory has to be divided into 8 bit wide blocks and the read and write ports have to be treated in a different way. The fitness case (data output of the read port) is a concatenation of values from all these blocks from the same address. When writing from the AXI bus side, at most 4 blocks are updated at the same time. The total memory size depends on the chosen pixel neighbourhood and the maximum training image size we want to use. In our design, the number of fitness cases is limited to 65,536 due to fixed address width (16 bit), then the maximum memory capacity is  $80 \cdot 65,536 \approx 5,243$  Kb for  $3 \times 3$ , respectively  $208 \cdot 65,536 \approx 13,632$  Kb for  $5 \times 5$  neighbourhood. Note that these sizes still fit into the Virtex devices, but not into the Zynq SoC (see Table 1).

Thanks to these hardware components, the fitness calculation is very efficient. The remaining steps of the evolutionary process (individuals manipulation, communication) take place on the MicroBlaze processors.

The evolutionary design is running as follows. At the beginning, original and noisy images are transferred to the external DDR3 memory, fitness cases are put together and copied to the CGP Memory. After that, the design process is initiated. Timing diagram in Figure 5 shows the steps of a single generation. The population is divided into  $N_{ch}$  chunks of  $P_{ch}$  individuals depending on the number of

Figure 8: Architecture of CGP Memory.

VRCs  $N_{VRC}$  and the population size  $P$ :

$$N_{ch} = \left\lceil \frac{P}{N_{VRC}} \right\rceil, \quad P_{ch} = \left\lceil \frac{P}{N_{ch}} \right\rceil. \quad (2)$$

In each generation, individuals belonging to the first chunk need to be mutated and transferred to the CGP Unit before the fitness computation is executed. For every succeeding chunk (except for the last one including the last individuals of the population), the mutations and chromosome transfers can be overlapped with the fitness computation (all chromosome registers are shadowed). To achieve the best hardware utilization, the fitness computation time  $t_f$  has to be longer than the time  $t_m$  spent on the mutations and transfers. Ignoring some overhead, the total time per generation  $t_g$  is than:

$$t_g = t_m + (N_{ch} - 1) \cdot \max(t_m, t_f) + t_f. \quad (3)$$

Finally, when the evolution is completed, the best individual's chromosome is sent to the PC.

The coevolutionary design process is slightly more difficult, as it can be seen in Figure 6. The image filter evolution is running almost the same way except for the fitness cases subset, which is being evolved in parallel. For the purpose of FCSs evaluation, the best evolved filters are saved to an archive of candidate filters. The FCSs evolutionary process

Figure 5: Timing diagram of the evolutionary process.

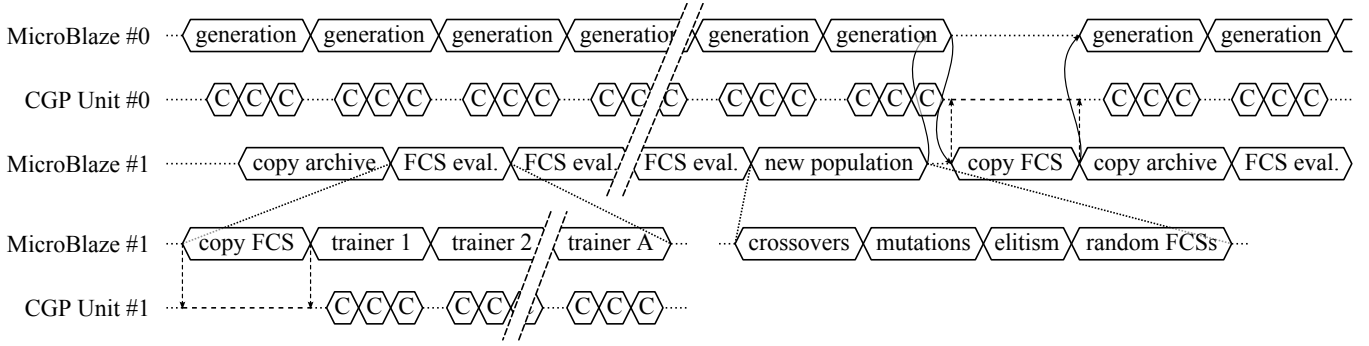

Figure 6: Timing diagram of the coevolutionary process.

is based on a simple genetic algorithm, the FCS chromosome is represented by a fixed-sized array of integers. In each generation, all FCS individuals are evaluated using all filters from the archive (trainers), the fitness value of the  $i$ -th individual is the mean value of the particular fitnesses:

$$f_{\text{FCS}}^i = \frac{1}{A} \sum_{j=1}^A f(i, j), \quad (4)$$

where  $A$  is the archive size and  $f(i, j)$  is the fitness (either squared error  $f_{\text{sq}}$  or absolute error  $f_{\text{abs}}$ ) of the  $j$ -th trainer on the  $i$ -th FCS. After all FCSs are evaluated, new population is created using standard genetic operators. Specified number of individuals is obtained by one-point crossovers and the new individuals are mutated with some probability. In order to exert the selective pressure, elitism is introduced by keeping the best individual unchanged and making a few mutated clones. Finally, the rest of the population is generated randomly to preserve genetic variability. At the end of each generation, the filter evolutionary process is notified and at the right moment (after finishing the entire generation), the FCS is copied to the CGP Unit #0. No FCSs sharing between MicroBlaze processors is required.

## Experimental results

This section presents benchmark problems, experimental setup and experimental evaluation of the proposed hardware accelerated approach and its comparison with the software approach.

In order to evaluate the proposed approach, salt-and-pepper noise filters were designed using standard CGP and coevolutionary CGP. This type of noise is characterized by noisy pixels with the value of either 0 or 255 (for 8-bit gray-scaled images). The Lena training image with size  $256 \times 256$  pixels was corrupted by 5%, 10%, 15% and 20% salt-and-pepper noise. The evolved filters were tested on 14 different images (Gonzalez et al., 2009) containing the same type of noise.

CGP was used according to Sekanina et al. (2011), i.e.  $n_c = 8$ ,  $n_r = 4$ ,  $l = 7$ ,  $n_i = 9$ ,  $n_o = 1$ ,  $\lambda = 19$ , every node had two inputs, the number of mutations per new individual was  $h = 5$  and  $\Gamma$  contained the functions from Table 2. The archive of candidate programs had capacity of 20 elements.

FCSs were evolved using a simple GA, where 3-tournament selection, single point crossover and mutation up to 2 % of chromosome were used. Elitism and random individuals were used to exert selective pressure and preserve genetic variability. For the GA, various chromosome lengths were tested, particularly, 1.5625 %, 3.125 %, 6.25 %, 12.5 %, 25 % and 50 % of total number of fitness cases in the training set. For each FCS size, 100 independent runs were performed and the evolution/coevolution was terminated after 100,000 generations of CGP.

The proposed coevolutionary algorithm accelerated using FPGA was compared with the standard CGP algorithm in terms of filtering quality of evolved filters and with the highly optimized coevolution implementation running on an ordinary processor in terms of the execution time.

The quality of filtering was expressed using a measure typically used in the image processing community – as a peak signal-to-noise ratio (PSNR):

$$\text{PSNR}(x, y) = 10 \log_{10} \frac{255^2}{\frac{1}{MN} \sum_{i,j} (x(i, j) - y(i, j))^2}, \quad (5)$$

where  $M \times N$  is the size of the image,  $x$  denotes the original image,  $y$  the filtered image and  $i, j$  are indexes of a pixel in the image. Figure 9 shows that using coevolutionary CGP running on an FPGA we are able to evolve image filters of comparable (or better) quality than standard CGP for all noise intensities. Furthermore, the higher the noise intensity, the smaller fitness cases subset can be used to get acceptable results.

Software and hardware performance comparison for standard CGP can be found in Table 3. The software implementation is a command line tool written in C++ utilizing OpenMP library for running in multiple threads and SSE 4.1 instruc-

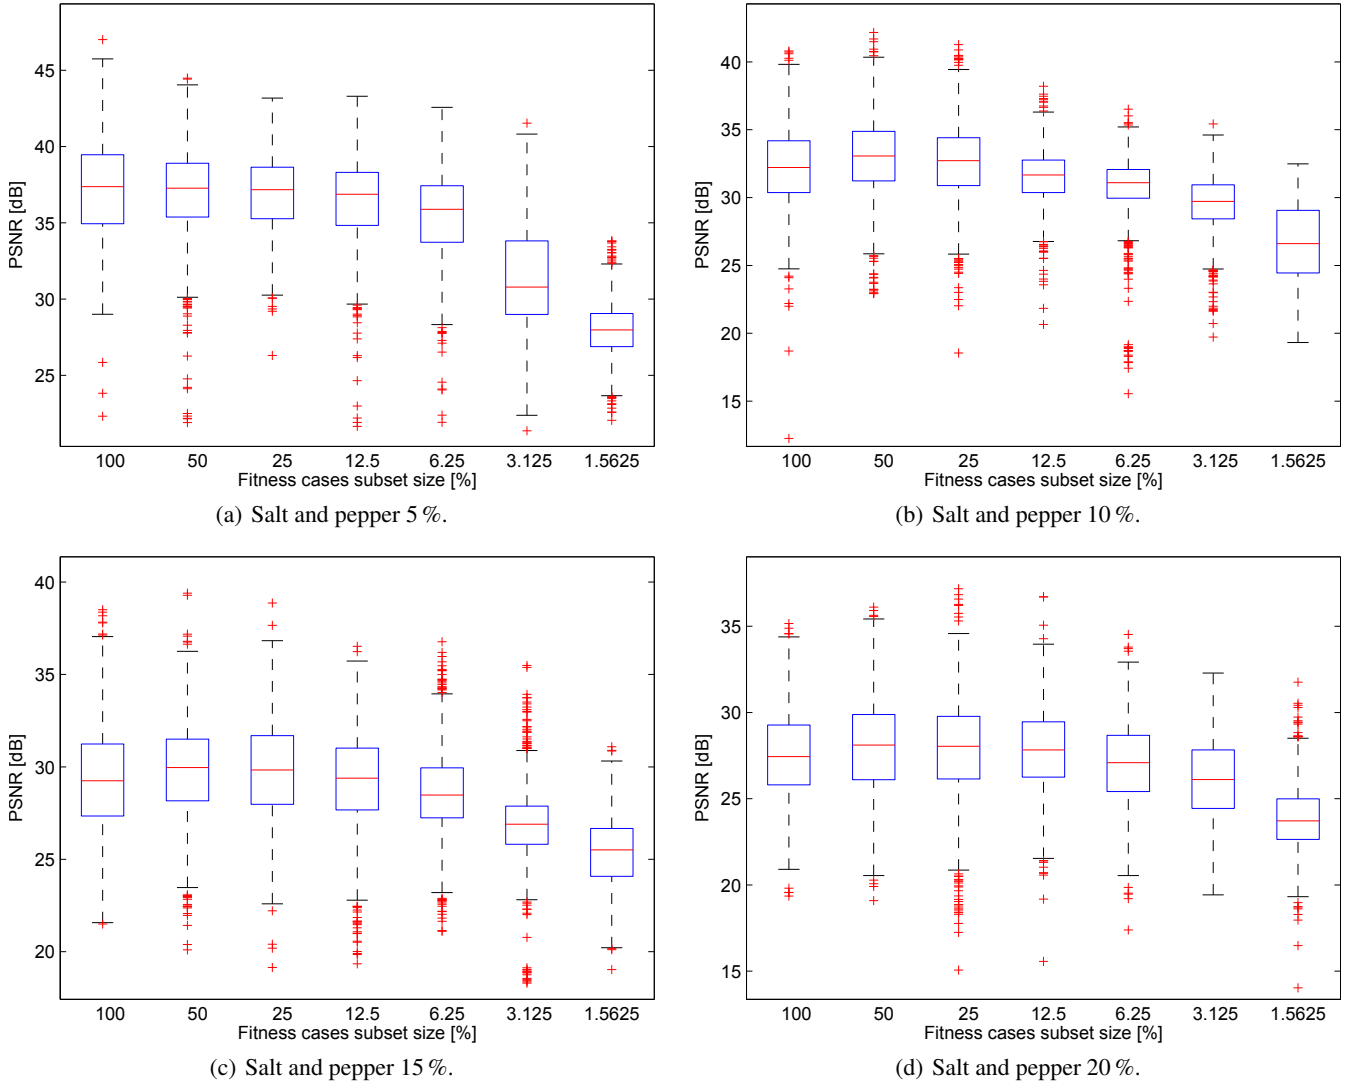

Figure 9: PSNR statistics calculated from 100 evolved filters (100 independent runs using the Lena training image for each noise intensity and each FCS size) for the 14 test images.

tions enabling to process 16 fitness cases in a single step. Before evaluation, each chromosome is analyzed to exclude the inactive nodes. The performance tests were performed on the Intel Core i7-860 processor (2.8 GHz), allowing 8 threads to be running simultaneously. The hardware platform configuration was as follows: 7 VRCs in the CGP Unit #0, 6 VRCs in the CGP Unit #1, in total  $N_{VRC} = 13$ , the entire system was running on 100 MHz frequency. Despite a very efficient software implementation and powerful processor, the hardware implementation overcomes the SW version significantly. The bigger the population, the higher the acceleration, while the most advantageous choice of the population size is a multiple of the VRC count.

The coevolutionary design performance of the hardware platform was compared to a software implementation, again

Table 3: Hardware platform evolutionary process performance (10,000 generations, image size  $256 \times 256$  pixels, 1-5 mutations per chromosome) obtained by running 100 independent tests for each population size.

population size	5	10	15	20	25
SW time (s)	30.83	74.65	122.39	183.40	233.71
HW time (s)	7.21	7.86	14.17	14.44	14.83
acceleration	4.28	9.50	8.63	12.70	15.77

optimized using OpenMP and SSE 4.1 instructions. Because of two evolutionary processes running in parallel and very poor data locality, the performance of the software implementation was vastly degraded. Therefore the speed-up

Table 4: Coevolutionary design performance.

FCS size	50 %	25 %	12.5 %
SW time (s)	713.23	405.47	223.18
HW time (s)	12.51	6.91	4.23
acceleration	56.99	58.64	52.82
FCS size	6.25 %	3.125 %	1.5625 %
SW time (s)	133.91	88.26	71.92
HW time (s)	3.57	4.20	3.97
acceleration	37.49	21.04	18.11

is much more significant in the case of coevolutionary design. Table 4 shows performance tests results for software and hardware approaches. The experimental setup was as follows: 10,000 generations, population of 20 individuals, image size  $256 \times 256$  pixels, 1-5 mutations per CGP chromosome, up to 2 % mutations per FCS. Note that for FCS sizes lower than 12.5 %, the evolution time is similar. Due to very low fitness cases count, the fitness computation time  $t_f$  is shorter than the mutations time  $t_m$  and hardware utilization goes down. Moreover, the FCS evolution runs faster due to lower overhead and the FCS is updated more often. That is why the computation time can surprisingly grow with FCS size decrease.

## Conclusions

In this paper, a hardware platform for coevolutionary CGP speed-up based on FPGA technology has been proposed. Two-population coevolutionary algorithm running on dual MicroBlaze soft processor system has been accelerated using custom peripheral based on virtual reconfigurable circuit approach. The full pipelined VRC along with a special fitness cases memory enables very efficient fitness calculation. The performance of the hardware was experimentally evaluated in the task of evolutionary image filter design. It was shown that using custom hardware, universal processor throughput can be greatly overcome in the task of the evolutionary design and even more in the coevolutionary case. Various sizes of fitness cases subset have been applied to demonstrate the coevolutionary approach benefits. Especially for higher noise intensities, reduction of the FCS size leads to better results.

With small modifications, the hardware platform can be used to effectively evolve other digital circuits using coevolutionary CGP. In our future work, we will focus on designing image filters for other noise types as well as other image transformations, combinational logic design and other tasks suitable for coevolutionary design.

## Abstract

Predator-prey interactions are the key element of ecological systems. We present the results of morphology-behavior predator-prey coevolution in a 3D physically simulated environment. The morphologies and behaviors of virtual creature predators and prey are evolved using a genetic algorithm and random one-on-one encounters in a shared environment. There are two levels of asymmetries in the model: One is between two species, predators and prey, and the other is between two traits in each species, morphology and behavior. We analyze and discuss the complex coevolutionary dynamics caused by the asymmetries on the basis of quantitative characterization of morphology and behavior.

## Introduction

Predator-prey interactions are the key element of ecological systems (Legreneur et al., 2012). Predation pressures in food chains shape diversity and functions of organisms (Agrawal, 2001). Many predators employ various strategies capturing their prey, and at the same time, many prey employ various protective mechanisms against their predators (Edmunds, 1974). These strategies arose through the coevolution between predators and prey. Furthermore, in the coevolution, morphology and behavior have been tightly coupled in each species. Therefore, the process can be regarded as double coevolution of morphology-behavior and predator-prey couplings (Fig. 1).

Figure 1: Double coevolution of morphology-behavior and predator-prey.

Predator-prey systems are conventionally studied in mathematical biology (population dynamics) using mathematical

methods (e.g., Lotka-Volterra equations) by analyzing evolutionary changes at the population level (Murray, 2003). However, these studies have not focused or have not been able to focus attention on coevolution of morphology and behavior of individual virtual creatures. On the other hand, virtual creature models in Artificial Life, following the pioneering study (Sims, 1994b), allow us to analyze the morphology and behavior coevolution in 2D and 3D environments (Ventrella, 1998; Taylor and Massey, 2000; Chaumont et al., 2007; Miconi and Channon, 2006; Pilat and Jacob, 2008; Turk, 2010; Azarbadegan et al., 2011). Additionally, due to the physical nature of the simulation, we are able to compare the resulting virtual creatures with biological organisms sharing similar morphological and behavioral traits (Chaumont et al., 2007). Some studies explored competitive coevolution in this framework (Sims, 1994a; Miconi, 2008). However, they have not focused on the morphology-behavior coevolution under the predator-prey coevolution and have not analyzed the strategies based on their morphological and behavioral characteristics.

The purpose of our study is to understand the evolutionary dynamics of the predator and prey strategies emerging in the context of this double coevolution. We perform double coevolution of morphology-behavior and predator-prey couplings by using a simple predator-prey scenario in a 3D physically simulated environment. As a first step of our investigation, we observed the emergence of various morphological and behavioral prey defensive strategies and found a weak tendency for the order of strategy emergence between morphologies and behaviors by using cross-correlation methods in the simulated environment (Ito et al., 2012, 2013). In this paper we give a simple quantitative characterization of morphology and behavior of each virtual creature. We track the evolutionary changes in special indices for both predators and prey species, specifically through the evolutionary process in which prey evolve one of the defense strategies, “Guard Strategies”. We then discuss the coevolutionary dynamics in terms of the asymmetries in the predator-prey and morphology-behavior relationships.

## Model

We use the Morphid Academy open-source simulation system (Pilat and Jacob, 2008) to evolve virtual creatures in a 3D physically simulated environment (Fig. 2). Morphid Academy has previously been used to successfully evolve virtual creatures for locomotion (Pilat and Jacob, 2008), light-following (Pilat and Jacob, 2010), and sustained resource foraging (Pilat et al., 2012). The presented coevolution of predators and prey provides an example of simulating several agents in a shared environment of Morphid Academy in a coevolutionary context.

Figure 2: Virtual creatures evolved in Morphid Academy.

## Agents

The agents are virtual creatures comprised of several 3D rectangular solid body parts connected with simple hinge joints. Their physical phenotype is developed from a directed graph (Fig. 3). The nodes represent body parts and the links represent joints.

The genotype graph undergoes evolution through a genetic algorithm. We termed the root body part as the *torso*, and all the other parts as *limbs*.

Figure 3: The development from genotype to phenotype.

The controller of a virtual creature is a recurrent neural network embedded in body nodes. There are three types of neurons: input, calculation and output. The input neurons represent sensory information from the environment,

the computational neurons process the input and the results are fed into the output neurons as joint effectors that power the joints, making the creature move. The creature sensor detects other living agents nearest to the virtual creature within a sensing range  $r$ . This virtual creature model is a simplification of Sims' Blockies model (Sims, 1994b) and is fully described in (Pilat and Jacob, 2008). The simplification in body and neural structure decreases the evolutionary search space and has been demonstrated to perform well for various evolutionary tasks.

## Experimental Environment

To represent a predator-prey encounter, we simulate a single prey creature with a single predator creature in a shared environment. A random prey creature is positioned near the origin of the simulation space. A random predator is then randomly positioned at  $r_0$  distance from the prey as shown in Fig. 4. Both agents are positioned above the simulation plane and allowed to free-fall due to gravity during a stabilization phase. Once they are stable from movement and resting on the ground surface, the evaluation encounter begins and lasts for  $S$  simulation time steps. Capturing is defined as the predator touching the torso of the prey with any of the predator's body parts. A captured creature is disabled and cannot be sensed.

Figure 4: Initial positions of a predator and a prey at the start of the encounter.

## Evolution

Two populations are concurrently evolved, representing the predators and the prey. A steady-state genetic algorithm is used with tournament selection of 3 predator-prey pairs.. Fitness of each agent is calculated from the result of an encounter between the randomly selected predator-prey pair. For each tournament, one or two individuals, per population, with the best fitness can produce a child through one of the genetic operators of copy, crossover or grafting. The child replaces the worst performing of the 3 individuals of the corresponding population (prey or predator). Mutation is applied to the resulting child individual and includes: mutation of the morphological nodes or link parameters, addition

of morphological nodes, and the addition or removal of morphological links.

### Fitness Functions

The fitness of each agent is calculated after the predator-prey encounter by a fitness function. The fitness of a predator is defined by Eq. 1. Fitness of 5000 is allocated if the predator has captured the prey with an additional maximum of 5000 points proportional to the capture time. If the prey is not caught, the fitness is proportional to the distance gained towards the prey, based on the initial distance  $r_0$  and the final distance  $r_n$ .

$$F_{pred} = \begin{cases} 5000 + 5000 \times \frac{t-t_n}{t} & (caught) \\ 5000 \times \frac{r_0-r_n}{r_0} & (missed, r_0 \geq r_n) \\ 0 & (missed, r_0 < r_n) \end{cases} \quad (1)$$

The fitness of the prey is defined by Eq. 2. If the prey escaped from the predator (not caught within the specified simulation time), it receives a fitness value of 5000 with an additional value of up to 5000 points proportional to the distance it moved  $l_n$ . Otherwise, the fitness is calculated according to the ratio of the time the prey escaped during  $t_n$  over the time limit  $t$ .

$$F_{prey} = \begin{cases} 5000 + 5000 \times \frac{l}{l_n} & (escaped, l_n \leq l) \\ 10000 & (escaped, 0 \leq l < l_n) \\ 5000 \times \frac{t-t_n}{t} & (caught) \end{cases} \quad (2)$$

### Morphological and Behavioral Indices

Two simple indices are used to characterize morphologies and behaviors of virtual creatures quantitatively and to track their evolution. We use the ratio of the volume of the torso to the total volume as a morphology index (hereafter referred to as MOR). The reason for this is that Guard Strategies are characterized to have big or many limbs protecting a small torso from being captured (Ito et al., 2012). It is more difficult to quantitatively characterize the behavior of virtual creatures to represent the progress of evolution since, in general, the behavior heavily depends on the morphology, which itself is difficult to quantitatively characterize. After conducting preliminary experiments using many candidate indices, we decided on a simple index: the average output of effector neurons (hereafter referred to as BEH), which is intended to approximately represent the mobility of virtual creatures approximately, and does not depend directly on the agent morphology.

## Result

### Parameters

We evolved predator and prey populations, each of size  $i = 30$  and initially random individuals, for  $g = 10000$  tournaments. Each evaluation of an encounter was performed for  $S = 100000$  simulation time steps with an initial distance  $r_0 = 700$  between the agents. For each tournament,

a child was created by asexual copy (probability of 40%), crossover (30%), or grafting (30%). Mutation of the child was performed with prob. of 80% with each mutation able to apply small changes to the whole genome (prob. of 5% per gene). The vision radius of predators was 5000 while the prey were only able to see within 500 distance units. Therefore, the predator is able to sense the prey much earlier than the prey.

In previous studies, we classified the evolved prey's defensive strategies into two types, each with an assortment of evolved morphologies and behaviors: Runaway Strategy which involves fleeing from the predator and Guard Strategies (*Turtle*, *Clam* and *Tower* types) which rely on their morphologies and typically stationary behaviors to provide protection from predation (Ito et al., 2012). It is easy to detect the emergence of the Guard Strategies as they tend to evolve with a sharp increase in the fitness. Therefore, we investigate the relationship between morphology and behavior evolution by focusing on the course of the evolution of Guard Strategies. To control the movement of prey and to promote the emergence of Guard Strategies, we used the modified fitness function of the prey (Eq. 2) and the environmental parameter  $l = 100$ .

### Coevolutionary Dynamics

We performed 30 trials, among which we observed that prey evolved some Guard Strategy (Fig. 5) to prevent predator capture in 17 trials. The prey did not seem to have evolved any defensive strategies in the other trials. We further observed 12 trials with a clear increase in fitness out of the 17 trials. Each of the 12 trials evolved a specific prey strategy: Tower (6), Clam (4), and Turtle (2).

Figure 5: Sample morphologies of the Guard Strategies.

Fig. 6 shows a typical evolution trial in which *Clam* type Guard Strategy emerged. The blue and red lines in the middle graph represent the average fitness of the prey and predators, respectively. Each of the top and bottom graphs (top: prey, bottom: predators) represents a distribution of virtual creatures in the space defined by the two indices (X-axis: MOR, Y-axis: BEH, both in a logarithmic scale after normalization). In these graphs, a circle represents an individual, with its radius proportional to its fitness. We can estimate that the individuals close to each other have similar phenotypes. Specifically, two individuals sharing the same X-coordinate have the similar morphological characteristics,

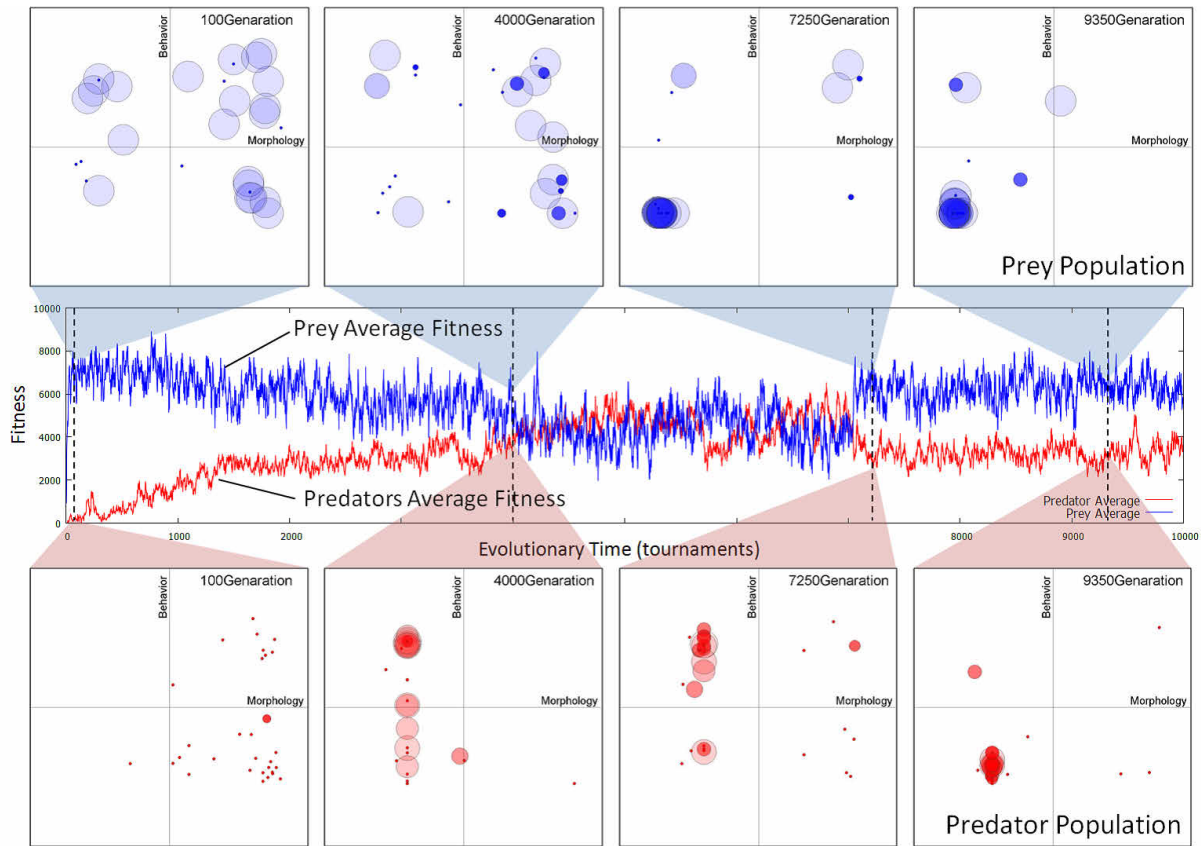

Figure 6: The evolution of the average fitness and the distributions of individuals on the trait space.

and sharing the same Y-coordinate corresponds to the similarity of their behaviors.

In early generations, the average fitness of the predator (prey) population was very low (high), which is also shown by the small (large) radius of the circles on the corresponding trait space. It corresponds to the situation in which the predators could not catch the prey at all. A wide distribution of the circles on the trait space of predators or prey reflects a wide variety of morphologies and behaviors of randomly generated individuals.

After that, until around the 4500<sup>th</sup> generation, predator fitness gradually increased while prey fitness slightly decreased. Large circles on the predator trait space, which represent the evolved predators, can be seen to create an elongated cluster, with data points having similar X-coordinates and a large variety of Y-coordinates. This indicates that the effective strategies that emerged in this predator population have similar morphological characteristics but diverse behavioral characteristics. In the trait space of the prey, the number of individuals with high fitness decreased while individuals with low fitness increased, as a consequence of the predator population's evolution. The tendency for some in-

dividuals of the prey population to maintain high fitness in this generation may be simply due to them encountering incompetent predators.

At some point near the 7000<sup>th</sup> generation, a switch in fitness performance occurred. This was due to the emergence of individuals with a strong defensive Guard Strategy, as shown in Fig. 8, which suddenly took over the population, represented as the reduction of the circle distribution on the trait space. Notice that when comparing the distribution of predators of the 7250<sup>th</sup> generation with that of the 4000<sup>th</sup> generation, there are many circles whose size decreased while their positions were the same. This means that although the major strategy of the predators (depending on a specific morphology) did not change between these two generations, they failed to catch the prey adopting the emerging Guard Strategy.

Finally, the cluster of the predators on the trait space shifted downward in 9350<sup>th</sup> generation. It means that the predators changed their strategy by adjusting their behaviors to adapt to the prey strategy. However, the prey population kept high fitness with their Guard Strategy unchanged.

### What Happened when a New Strategy Emerged?

Here we present a method to investigate the dynamics of morphology-behavior coevolution. We track the evolving populations especially when Guard Strategy emerged, by sequentially plotting the average position of the population of predators or prey on the trait space. The fitness-weighted center is used when calculating an average position. Note that we ascribed the fitness to the weight when we calculated the center of the mass. What we see from the coevolutionary trajectory and the fitness transitions includes the evolutionary order of the emergences of new or improved morphology and behavior.

Figure 7: A typical evolutionary trajectory on the trait space when Guard Strategies (*Clam* and *Turtle* types) evolved in the prey population.

Figure 8: The virtual creatures with the best fitness in each generation appearing in the evolution trial shown in Fig. 7. The right three individuals have obtained the guard strategy and are the offspring of the left one.

Fig. 7 and 9 show the two typical evolutionary trajectories

when Guard Strategies emerged. The horizontal and vertical movements correspond to the morphological and behavioral changes of the prey population, respectively. Therefore, we can estimate that Fig. 7 shows that the morphological changes preceded the behavioral changes when the defense strategy was acquired, in other words, the morphological characteristics of the strategy spread in the population before behavioral characteristics spread. Fig. 8 shows an ancestor and its three offspring prey with Guard Strategy in this evolution trial, all of which obtained the best fitness in each generation.

On the contrary, Fig. 9 shows roughly that the behavioral changes preceded the morphological changes. Fig. 10 shows an ancestor and its three offspring prey with Guard Strategy in this evolution trial, all of which obtained the best fitness in each generation. They are characterized as its immovability as compared with the creatures shown in Fig. 7.

Figure 9: A typical evolutionary trajectory on the trait space when Guard Strategies (*Tower* type) evolved in the prey population.

It should be noticed that, as a general tendency of the step-wise evolutionary process, the fitness did not increase necessarily in accordance with the evolution of morphology or behavior. Instead, it clearly increased when either morphology or behavior was improved, which followed the evolution of the other. This observation tells us about close coupling between morphological and behavioral evolutions in the emergence of new strategies.

The difference in the evolutionary order of new trait emergence at least partly depends on the characteristics of evolved strategies. Guard strategies can be classified into the mobile and immobile ones. The former and the latter

Figure 10: The virtual creatures with the best fitness in each generation appearing in the evolution trial shown in Fig. 9. The right three individuals have obtained the guard strategy and are the offspring of the left one.

correspond to the creatures in Fig. 8 (*Clam* and *Turtle* types) and Fig. 10 (*Tower* type), respectively. In general, immobility tends to need a specific sort of behavior while keeping some degree of freedom of their morphology. This might be the cause of the particularity of the emergence of the *Tower* type strategy in the context of the evolutionary order of the trait evolution. We will discuss the relationships between asymmetric properties and evolutionary dynamics in more general sense in the next section.

## Discussion

This paper demonstrates that we can observe the complex coevolutionary dynamics that takes place concurrently at predator-prey and morphology-behavior levels in a 3D physically simulated world. We discuss here that its complexity arises at least partly from the asymmetric properties in these relationships.

### Dynamics Caused by Population-Level Asymmetry

The predators were required to perform the following sequence of behaviors in the experiments: detecting a prey, approaching it, and then touching its torso part. Especially, successful methods for approaching need better morphology and behavior realizing faster movement and quick direction change, despite the fact that the bodies of both predators and prey are constructed and controlled by the same rules described in the Model section. In contrast, a prey adopting a simple strategy, such as moving forward in some direction, could be rather strong. Therefore, in general the selection pressure is considered stronger in the predator population than in the prey population. This asymmetry is not specific to our model but universal in natural ecosystems.

In the experiments, we frequently observed a typical coevolutionary dynamics “arms race” in which two evolving populations reciprocally drive one another to increasing levels of complexity. It was clearly shown that the asymmetry in the difficulty of required strategies caused the preceding evolution of the predators. The coevolutionary dy-

namics always started with the acquisition of the capturing strategies by predators as described in the previous section. This is due to the fact that the selection pressure acted more strongly on the predators in the initial stage in which both populations were occupied with randomly generated strategies. The prey started devising strategies in response to the increase in the selection pressure caused by the emergence of the effective strategies of the predators. A typical evolutionary scenario following the initial stage was regarded as a step-by-step evolution composed of several repetitions of alternate strategy improvement corresponding to the previous improvement of the other population. We also found in the experiments that the required time for predators to find or improve their strategies tended to be longer than in the case of prey. This is also due to the asymmetry between the predator-prey relationships.

### Dynamics Caused by Individual-Level Asymmetry

When comparing the changes in morphology and those in behavior, our impression, based on the experience with the coevolutionary experiments, is that a morphological change (e.g. the loss/growth of the limbs) tends to bring about a drastic change in the strategy. If this hypothesis is correct, a change in morphology and that in behavior in evolution correspond to an operator for global search and that for local search in the context of optimization problems. In other words, the morphology evolution has a potential to be a driving force to break away from the stalemate and in contrast, the behavioral evolution has a role to adjust the performance of the current strategy.

This hypothesis agrees well with the experimental results as follows. As for prey strategy evolution, we usually observed an emergence of an effective defense strategy characterized by a unique morphology, accompanied with a sharp increase in fitness. As for predator strategy evolution, we observed an emergence of a novel morphology that was followed by a gradual behavior evolution with the diversity in behavior, producing a gentle increase in fitness. However, only in the case of responding to the emergence of a novel prey strategy, behavior evolution played a great role compared with morphology evolution. These results can be further generalized as a hypothesis for morphology-behavior coevolution. Morphology evolution tends to precede behavior evolution in the case the evolution is rather independent of the other species evolution, while behavior evolution tends to precede or work dominantly in the case the evolution is responsive to a novel strategy evolved in another species. This hypothesis is also supported by previous results (Ito et al., 2013).

## Conclusion

We presented the results of evolutionary experiments investigating morphological and behavioral dynamics of a coevolutionary predator-prey scenario in a 3D physically simu-

lated environment. We defined a number of indices to quantify aspects of the morphologies and behaviors of our creatures, and used these to analyze the coevolutionary dynamics. The evolutionary dynamics of the strategies showed an “arms race” between the predators and prey, a typical feature of natural coevolutionary scenarios. We also temporally analyzed the coevolutionary dynamics of the morphology and behavior, focusing on the order in which new traits emerge. Our results illustrate how double coevolution, between predator and prey on the one hand and morphology and behavior on the other, can lead to asymmetrical development of morphology and behavior at both the intra-species level and the inter-species level. These two asymmetries led to complex coevolutionary dynamics in our 3D physical simulated framework, and likely do so in predator-prey interaction scenarios in general, both in artificial frameworks and in nature.

Our model could be extended in various directions. One obvious direction would be to use a scenario with many-to-many encounters. Such evolutionary experiments may shed light on the origin of group hunting and prey herding behaviors that are prevalent in the biological world (Sumpter, 2011). Furthermore, this direction might add a new direction to understanding the effect of the phenotypic change on the population dynamics (Pimentel, 1961; Rosenzweig and MacArthur, 1963). Another direction would be to investigate how the dynamics of double coevolution concentrated on in this paper can be applied in the field of engineering, including evolutionary robotics.

## Abstract

Two variants of biologically inspired cell model, namely eukaryotic (containing a nucleus) and prokaryotic (without a nucleus) are compared in this research. Experiments are designed to provide an understanding of how the evolved regulation of protein transport to and from the nucleus of the eukaryotic type cell gives rise to complex temporal dynamics that are not achievable in a prokaryotic cell.

A novel system of protein movement based on the process of nucleocytoplasmic transport observed in the biological eukaryotic cell is proposed. Nucleocytoplasmic transport is considered by biologists to be one of the most important factors when determining the developmental trajectory of a cell, as it allows for additional control of transcription factors entering the nucleus, thereby regulating gene activity.

Experiments contrast the ability of both cell models to generate protein patterns within the cytoplasm. Results demonstrate that the additional cell complexity of the eukaryotic does not impede the Gene Regulatory Networks control. For increasingly difficult tasks requiring precise temporal control the performance of the eukaryotic cell model outperforms the prokaryotic cell model. In addition, results demonstrate that the second level of regulation introduced by the transport process within the eukaryotic cell allows very precise control of gene activity and provides the EA with a source of heterochronic control not possible in prokaryotic-type cells.

## Introduction

Cells are the fundamental building blocks of all biological life. Two distinct groups of cell exist, eukaryotic and prokaryotic. Eukaryotic cells are distinguished by the separation of the cell into compartments, the most pronounced compartment, the nucleus contains the genome (Figure 1). The genome is decomposed into genes, which encode the blueprint for creating the organism. During the process of development gene expression results in the creation of proteins levels within the cells. Proteins within the cell direct and dictate the cell fate and define its final role within the organism.

In order to enable gene expression, specialised proteins termed *Transcription Factors* (TF) must bind the gene cis-regulation sites. In response to TF binding, the gene expres-

Figure 1: Architecture of the eukaryotic cell model. The nucleus is composed of the Nucleoplasm, Genome, and Nuclear Pore Complex (NPC)

sion rate is regulated, influencing protein levels within the cell. The presence of a nucleus within eukaryotic cells (Figure 1) restricts direct entry of transcription factors to the nucleus. Transport across into the nucleus through the *Nuclear Pore Complex* (NPC) is enabled by specialised *chaperons* proteins binding to TF proteins. The chaperon proteins are subdivided into two categories *importins* which enable import to the nucleus, and *exportins* which enable export from nucleus to cytoplasm across the NPC. *Importins* bind specific sites on the TF, named *Nuclear Localisation Sequence* (NLS). Export from the nucleus is enabled by the binding of *exportin* to *Nuclear Export Sequence* (NES) associated with the TF. This network of interacting genes and proteins is known as the Gene Regulatory Network (GRN).

Modifications to the relative timing of developmental events are termed *heterochronic*. Lee and Hannink (2003) report that the control of protein entry to the nucleus provides a powerful mechanism for the temporal regulation of gene expression. West-Eberhard (2003) highlights the importance of heterochronic control as a source of phenotypic novelty

“if I could control the time of gene action I could cause the fertilised snail egg to develop in an elephant”

Heterochronic change is not a developmental process but rather an evolutionary process (West-Eberhard, 2003). Modifications to the timing of events are heritable and must be somehow linked to the genetic encoding.

Artificial developmental systems have been introduced as a technique aimed at increasing the scalability of Evolutionary Algorithms (EA) (Haddow and Hoye, 2007). These

systems seek to solve the problem of scale by replacing the linear genotype-phenotype mapping, with a non-linear mapping. However, developmental mappings have a low degree of evolvability caused by high degrees of epistatic interactions at the genotypic level (Van Remortel et al., 2003). Enhancing the ability of the genome to allow for heterochronic mutations increases the number of successful genotypes (Stanley and Miikkulainen, 2003) by offering a variety of paths to each successful phenotype.

This paper presents an Artificial EvoDevo (AED) platform capable modelling evolutionary and developmental processes within biologically plausible eukaryotic and prokaryotic cells. The prokaryotic cell model is based on the work of (Kumar and Bentley, 2003). Experiments compare the ability of the evolved GRNs within the cell models to control gene expression for a number of static, periodic and aperiodic objectives. Results demonstrate an increased evolvability of eukaryotic cells compared to the prokaryotic cell model. Analysis of gene activity within the GRN shows that the transport process is instrumental in increasing evolvability by providing efficient heterochronic control of gene activity.

The structure of the paper is as follows: Section 2 provides a review of the use of developmental processes by the ALIFE community. Section 3 describes the Artificial EvoDevo (AED) platform developed, the eukaryotic cell model and its associated transport process. Section 4 describes a series of experiments and analyses the GRN dynamics of both eukaryotic and prokaryotic cell models. Section 5 concludes the paper.

## Background and Existing Research

This section provides a review of the use of developmental processes by the ALIFE community. Much of the research on developmental mappings has been motivated by the fact that the process of development is seen as a possible solution to the problem of scale in Evolutionary Algorithms (EA) (Bentley and Kumar, 1999), (Haddow and Hoye, 2007). By combining EAs with a developmental mapping between genotype and phenotype, the linear relationship between both is removed. Introducing developmental mappings also reduces the causality between genotype and phenotype spaces, which can reduce evolvability since regions of the search space become unreachable (Roggen and Federici, 2004).

The process of development is primarily a temporal one, where development starts from a single point and over time expands into a series of parallel pathways (Raff, 1996). Temporally shifting these processes relative to each other can give rise to phenotypic novelty. These shifts in the timing of events are termed *heterochronic mutations*, and must be heritable between generations. Efforts by the ALIFE community to identify sources of heterochrony within developmental encoding are limited. Matos et al. (2009) adapts

the framework proposed by Albrecht et al. to quantify the degree of heterochrony achievable by both grammar based and cellular ontogenies. At the biologically plausible GRN level, Banzhaf and Miller (2004) illustrate a possible genetic mechanism by which heterochrony can be enacted. This is due to an encoding of time and strength of gene expression into the strength of interaction between transcription factors and the genes cis sites. Kumar and Bentley (2003) suggest that the modification to the diffusion rate of signalling proteins can also provide a degree of heterochrony.

The developmental model proposed by Kumar and Bentley (2003) is the primary source of inspiration for the AED platform described in this paper. Using a prokaryotic cell model (Kumar and Bentley, 2003) demonstrate how intricate gene regulatory networks can be evolved to establish and control protein concentrations within a single cell. Furthermore they demonstrate the ability of the system to evolve 3D multicellular spherical morphologies.

This paper recreates the work of Kumar and extends it by introducing a eukaryotic type cell within the AED platform. Experiments contrast the evolved developmental processes within both cells by comparing the ability of the GRN to regulate protein concentrations for a variety of increasingly difficult static, dynamic and aperiodic objectives.

## The Artificial EvoDevo (AED) Platform

This section describes the developed Artificial EvoDevo (AED) platform, the eukaryotic cell model and its associated transport process. The section is decomposed into the following subsections - AED architecture and configuration, development and the cell cycle, protein model and classification, protein transport, mechanics of gene expression and the evolved genome structure.

The developmental algorithm within the AED platform captures the concepts of genes, proteins and cells. Similar to its biological counterpart, development proceeds along a time-line, where as a result of the GRN activity protein levels are established within the cell.

## AED Architecture and Configuration

The AED comprises two main components (Figure 2) the Genetic Algorithm (GA) and developmental algorithm. Evolved genomes are supplied by the Genetic Algorithm (GA) to the developmental algorithm. The genome is then developed by placing it inside a user selected cell type (eukaryotic or prokaryotic) and returns a fitness to the GA.

The user configures the AED via a configuration file (Table 1). In order to start the developmental process, maternal proteins are placed inside the cell. The biological counterpart of this process is fertilisation of the embryo. Seeding involves placing a single TF inside the cytoplasm. In the reported experiments this has been arbitrarily chosen as protein 0 with a concentration of 0.5. Eukaryotic type cells

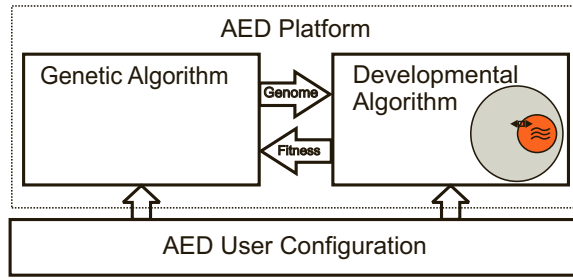

Figure 2: Architecture of the AED platform

are also seeded with *importins* (IM) and *exportins* (EX) type proteins at a concentration of 0.5.

### Development and The Cell Cycle

Having seeded the cell with maternal proteins evolved genomes are developed by executing a *cell cycle* Figure 3. The developmental process is executed for a user defined number of *steps* (Table 1a), by iterating the cell cycle shown in Figure 3. At the end of development, protein levels within the cell cytoplasm are used to determine the genotype fitness. The calculated fitness value is subsequently fed back to the GA (Figure 2), where the corresponding genome is then subject to evolutionary control.

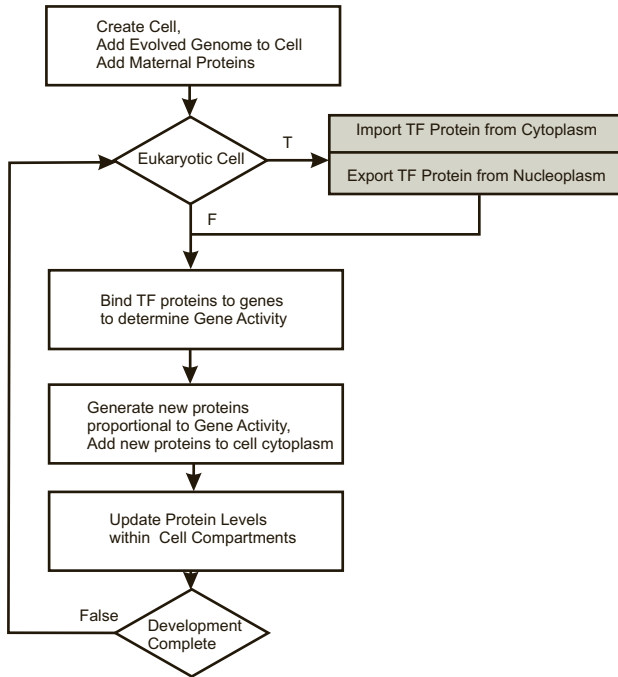

Figure 3: AED Cell Development Cycle

### Protein Model and Classification

The AED eukaryotic cell model contains three proteins classes (Table 2) while the prokaryotic model contains only

steps	200	Defines the # Development Steps
ntf	3	Number of TF's
nim	3	Number of Importins
nex	3	Number of Exportins

(a) Developmental Algorithm Configuration

runs	50	Number of GA runs
gens	4000	Number of generations per run
psize	100	Population size
pmut	0.1	Mutation Rate
tsize	20	Tournament Size
pxo	0.6	Probability of crossover
obj	Sin	Objective
tps	2	Number of test proteins

(b) Genetic Algorithm Configuration

Table 1: Typical Configuration Parameters used by the AED platform. The settings listed are typical for the experiments reported in this paper.

a single TF type protein. Details of the three protein classes are listed in Table 2. Proteins are distinguished by a *protein code* derived from the gene code (Figure 4). There is a direct mapping between gene code and protein code, ie. gene code 1 maps to protein code 1 etc. The relationship between protein IDs and protein class (TF, IM, EX) is determined by the user setting of *nim*, *nex* and *ntf* in the configuration file listed in Table 1a.

Protein Class	Description	ID Range
Transcription Factor (TF)	regulates gene activity	$0 \rightarrow ntf - 1$
Importin (IM)	enables TF import	$ntf \rightarrow ntf + nim - 1$
Exportin (EX)	enables TF export	$ntf + nim \rightarrow ntf + nim + nex - 1$

Table 2: Protein Class Names and their corresponding function. The ID range of the protein types are calculated based on the user configuration of Table 1

### Protein Transport

In eukaryotic cells TF type proteins must be first transported into the nucleus in order to regulate the rate of gene expression. TF proteins within the AED model include additional evolved NLS and NES regions, (Figure 4). Binding of IM/EX type proteins to these sites enables transport of the TF between compartments. During the transport phase of the cell cycle (Figure 3), each TF is selected and the proportion of protein exported  $C_{ex}(tf)$  and imported  $C_{im}(tf)$  is described by (1 and 2) respectively.

$$C_{ex}(tf) = TF_{nuc} * f(TF_{nuc} * W_{TF} + \sum_i^n (Ex_i * NES_i)) \quad (1)$$

$$C_{im}(tf) = TF_{cyt} * f(TF_{cyt} * W_{TF} + \sum_i^n (Im_i * NLS_i)) \quad (2)$$

where  $f$  is defined as the sigmoid function, with  $TF_{nuc}$  and  $TF_{cyt}$  being the concentrations of the selected TF in the nucleus and cytoplasm compartments respectively.  $W_{TF}$  is an evolved bias for the selected TF.

Export Control (NES)			4
0.1	-0.8	0.1	
0.2	-0.9	0.3	
Import Control (NLS)			Protein Code

Figure 4: The evolved NLS and NES sequences associated with each TF

### Mechanics of Gene Expression

Upon entering the nucleus the rate of gene expression (GE) is regulated by the binding of TF protein to the cis-regulatory sites of individual genes. For each gene encoded on the genome the expression rate  $GE_n$  is described as (3).

$$GE_n = SR_n * f\left(\sum_{i=0}^n I_n * TF_n - TH_n\right) \quad (3)$$

where  $SR_n$  is the evolved max synthesis rate for the gene,  $TH_n$  and  $I_n$  are the evolved gene threshold and interaction levels respectively. All protein produced during the gene expression phase is placed within the cytoplasm and any existing protein concentration ( $C_{n-1}$ ) is updated (4).

$$C_n = C_{n-1} - (C_{n-1} * DR) + GE_n \quad (4)$$

where  $DR$  is the evolved decay rate for this protein.

### The Evolved Genome Structure

The role of the GA is to provide candidate configurations (genomes) to the developmental algorithm. Following the development process these configurations are assigned a fitness. The GA is a derivative of the standard generational GA with elitism, gaussian mutation, uniform crossover and tournament selection. All parameters for the GA and development algorithms are user selectable via the configuration file (Table 1). The genome is subdivided into two chromosomes, with each chromosome subsequently decomposed into genes. The genes contained on the first chromosome exclusively encode the protein information for all 3 protein classes (TF, IM, EX). Genes on the second chromosome encode the transport specific information (NLS/NES) for each of the TF proteins (Figure 4). Figure 5 illustrates the structure of the genes contained on each chromosome.

### Experiments and Results

This section describes a series of experiments and analyses of the GRN dynamics of both the eukaryotic and prokaryotic models. The experiments compares the abilities of the GRNs within eukaryotic and prokaryotic models to

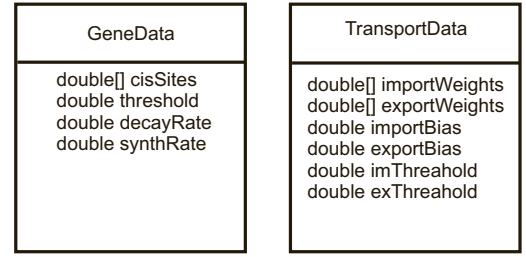

Figure 5: UML diagram of genes encoded on the 2 chromosome within eukaryotic cells.

evolve and follow defined protein patterns during their development. The objectives selected for the comparison are divided into three categories in order of increasing difficulty, namely static, periodic and aperiodic (Table 3). By contrasting the fitness achieved for the three classes of objective, allows a preliminary assessment of the contribution of transport within eukaryotic cell types.

Objective Name	Class
Lin	Static
Sin, Rect,	Periodic
Gauss, SinOff, GaussOff, AmpGauss	Aperiodic

Table 3: Objective Names and their corresponding classification

The simplest static objectives determine the fitness at the end of the developmental cycle, ignoring the concentration profile of the protein during the developmental cycle. For the static objective the fitness function is similar to that used by Kumar (5).

$$Fitness = \sum_{j=0}^{M-1} (C_j - (1 + j)/M)^2 \quad (5)$$

where  $M$  is the total number of transcription factor proteins under test and  $C_j$  is the concentration of protein  $j$  at the end of development.

In contrast both periodic and aperiodic objectives assess the fitness over the entire developmental time. Periodic objectives are designed to mimic their biological equivalent, termed circadian rhythms, where two proteins oscillate in lockstep. The aperiodic objectives, represent another biologically plausible objective as they place a precise temporal dependence on gene expression. In all test cases the number of proteins tested against the fitness function can be specified, up to the maximum number of transcription factors. Thus the fitness function for dynamic and aperiodic objectives is defined as (6).

$$Fitness = \sum_{j=0}^{M-1} \sum_{i=0}^n (O_{ji} - C_{ji})^2 \quad (6)$$

where  $C_{ji}$  is the concentration of protein  $j$  at time  $i$ , and  $O_{ji}$  is the objective concentration.

For each of the seven objectives tested the AED platform, was typically configured as per Table 1.

### Comparison of Eukaryotic and prokaryoticCell Dynamics

Results for each of the seven objectives (Table 3) are listed in Table 4. These results illustrate that both cell configurations can solve static and dynamic tasks with a high degree of accuracy. For the aperiodic objectives the eukaryotic type cells configurations show a considerable improvement over the prokaryotic cells. This improvement has its origins in the ability of the eukaryotic cell to limit the target protein activity to the specific times during the development. In contrast, the prokaryotic cells tends to have a continuous level of protein present at all times. Figure 7 illustrates the phenotype (protein levels within the cytoplasm) associated with each of the aperiodic objectives.

Fitness Results			
Objective	Nucleus	Best	Mean
Lin	T	0.0	0.092
	F	0.0	0.041
Sin	T	0.046	199.7
	F	0.058	250.95
SinOff	T	1.05	1288.71
	F	20.67	1415.8
RectSin	T	0.802	142.2
	F	1.31	131.13
Gauss	T	0.60	601.6
	F	4.765	785.39
GaussOff	T	0.855	590.25
	F	9.529	722.57

	F	3.83	432.05

Table 4: Results for Objectives, the presence of a nucleus indicating a eukaryotic type cell is shown by the Boolean [T]rue.

### Results Analysis: Gene Activity

The section illustrates how the process of transport within the eukaryotic cell is instrumental in generating the protein profiles associated with the aperiodic genome solutions. The level of gene activity for each of the individuals developed in Figure 7 is plotted in Figure 8. Because the gene ID corresponds to the proteins ID any variation in gene activity results in a corresponding change in its protein level.

Gene activity for the prokaryotic cell configuration (Figure 8 b, d, f) shows continuous activity over the entire development time, which is penalised by the aperiodic objectives. The close coupling between the genes and proteins in the prokaryotic cell makes it difficult to generate the isolated the gene activity required for the aperiodic objectives. This

coupling arises as a consequence of the genome and proteins being contained in the same cell compartment.

In contrast the eukaryotic cell achieves very specific regions of gene activity for genes 0 and 1 with relative ease (Figure 8 a, c, e). The regions of activity for genes 0 and 1 are very localised to the required times for peak protein activity within the cytoplasm. Inspecting the gene activity for the IM genes, (IDs {3, 4, 5}) and EX genes (IDs {6, 7, 8}) shows very broad and intense levels of activity, indicating that the process of transport is very heavily involved in the generation of the target protein profile.

The dynamics of the *Gauss* profile in Figure 8 e deserve special mention, as there is little or no activity on Gene 0 around the peak presence of protein 0 in the cytoplasm. Figure 6 illustrates that the protein profile is generated as a result of exporting the stored protein 0 from the nucleus at the appropriate time, Figure 6.

Figure 6: Protein 0 Dynamics for GaussOff Objective, illustrates the accumulation of Protein 0 in the nucleus prior to time step 20, while there is no gene activity around peak evaluation time, the cytoplasm protein profile for protein 0 is generated by exporting proteins from nucleus during this time.

### Results Analysis : Transport as a source of Heterochrony

This section investigates how mutations to the transport chromosome affect the quality of the aperiodic solutions. Selecting the best eukaryotic individuals from the *gaussOff* and *ampGauss* objectives illustrated in Figures 7 c, e the activity of the transport specific genes (ID 3-8) is reduced ('knocked out'), according (7) -

$$\text{GeneActivity} = KO * SR * \text{sigmoid}(\text{activity})$$

$$\text{where } KO \in A = \{0.9, 0.8, 0.5, 0.1\} \quad (7)$$

Figure 9 illustrates the full spectrum of heterochronic mutations are possible. For the *ampGauss* objective the level

of protein 0 (Figure 9c), increases its level and duration in the cytoplasm in response knock out. The level of protein 1 remains relatively unaffected but its onset is delayed in response to knock out (Figure 9d).

For the *GaussOff* objective (Figure 9a) the level of protein 0 is reduced in response to increasing knock out while the onset of protein 1 occurs earlier in the development (Figure 9b).

In addition to reducing the activity level the transport specific genes, the NLS/NES interaction levels could also have targeted to give similar results. From an evolutionary perspective, mutations to the transport chromosome have a causal relationship to the generated phenotype allowing the conclusion that the addition of the transport process, which is in effect a second level of regulation tends to provide a smoothing of the phenotype landscape.

## Discussion and Conclusions

The regulated entry of *transcription factors* to the nucleus of eukaryotic type cells has been shown to have a major influence on the direction of biological development. This paper has reported a biologically inspired eukaryotic cell model that captures the concept of regulated protein transport to and from the cell nucleus. Tests on the evolvability of the GRN indicate that the addition of this level of complexity does not prevent the cell successfully generating GRN dynamics. Indeed, it serves to improve the GRNs ability to

evolve aperiodic objectives. Analysis of the gene activity within the eukaryotic cell shows that it relies heavily on the transport of TF to and from the nucleus to control gene activity. In particular it is observed that for aperiodic tasks TF protein is only present in the cytoplasm at the required development time intervals. In contrast, while the prokaryotic-cell model fared well for static and periodic tasks, its performance suffered significantly for aperiodic objectives. An examination of the gene activity within the prokaryotic-cell model has shown continuous levels of gene activity during development time. In contrast, the eukaryotic cell isolates its gene activity to very specific regions of the development time. The high levels of activity for the IM/EX genes indicates their importance in generating the protein dynamics. The eukaryotic cell model demonstrates the potential for heterochronic mutations to arise by scaling the activity of transport specific genes. Moreover a high degree of correlation between the level of disruption to these genes and the resulting change in protein profile has been observed.

## Abstract

The ability to actively forage for resources is one of the defining properties of animals, and can be seen as a form of minimal cognition. In this paper we model soft-bodied robots, or “animats”, which are able to swim in a simulated two-dimensional fluid environment toward food particles emitting a diffusive chemical signal. Both the multicellular *development* and *behaviour* of the animats are controlled by a gene regulatory network (GRN), which is encoded in a linear genome. Coupled with the simulated physics, the activity of the GRN affects cell divisions and cell movements during development, as well as the expansion and contraction of filaments connecting the cells in the swimming adult body. The global motion that emerges from the dynamics of the animat relies on the spring-like filaments and drag forces created by the fluid. Our study shows that it is possible to evolve the animat’s genome (through mutations, duplications and deletions) to achieve directional motion in this environment. It also suggests that a “minimally cognitive” behaviour of this kind can emerge without a central control or nervous system.

## Introduction

In biological multicellular organisms, the dynamics of gene regulatory networks (GRNs) controls not only the growth of the organism, including the maintenance of the cells and overall structure, but also its behaviour. A striking example can be observed in social amoeba such as *Dictyostelium* (slime mold), where gene regulation controls both the aggregation of single cells into a slug and the adaptive behaviour of this collective entity (Bonner, 2008).

In theoretical biology and artificial life, artificial gene networks are used to understand how computational properties of biological networks evolve. One area of research is the evolution of control of multicellular development (Dellaert and Beer, 1996; Eggenberger Hotz, 1997; Doursat, 2009; Schramm and Sendhoff, 2011), another is computation in a more general sense (Banzhaf, 2003; Nicolau et al., 2010; Lopes and Costa, 2012). We addressed these two areas in our previous research using the artificial life system that we created, GReaNs (for Genetic Regulatory evolving artificial Networks; reviewed in Joachimczak and Wróbel, 2011). We investigated in particular the evolution of signal processing

using continuous or spiking computational units (Joachimczak and Wróbel, 2010; Wróbel et al., 2012), and the evolution of soft-bodied artificial organisms, or “animats”, whose development and locomotion were controlled by a GRN (Joachimczak and Wróbel, 2012; Joachimczak et al., 2012).

The use of a developmentally inspired stage to generate the morphology of a virtual robot is an active area of research, involving a range of abstractions for cellular and genetic control (Hornby and Pollack, 2002; Bongard and Pfeifer, 2003; Kowaliw et al., 2004; Doursat, 2008; Meng et al., 2011). The main contribution of our system lies in the combination of a biologically realistic encoding of the GRN (and genetic operators that allow for their complexification) with a realistic physics simulation. Physics rules govern the movement of cells during development, and the drag forces during locomotion in the fluid. Although in our current implementation the environment and the animats are two-dimensional, the system could be extended to 3D to make our results even more relevant. Physically plausible robots could take advantage of their softness—and thus resistance to damage and external forces—when interacting with other objects (for example, changing shape to squeeze through small openings). Although the properties of non-rigid, modular bodies have been explored before (Shimizu et al., 2005; Umedachi et al., 2010; Schramm and Sendhoff, 2011; Doursat et al., 2012; Hiller and Lipson, 2012; Rieffel et al., 2013), including our previous work on the diversity of locomotion strategies in soft-bodied animats (Joachimczak et al., 2012), the present study is the first attempt, to our knowledge, at evolving a fully decentralized controller and morphology of elastic animats that can sense and navigate their environment.

In the present paper we consider the evolution of gene regulatory networks able to control both the development of a soft-bodied animat and its emergent *multicellular chemotaxis*, a basic behaviour that consists of moving toward the source of an external signal. Despite its apparent simplicity, this task requires generating motion and coordinating numerous local cell actions to turn the body in the direction of a gradient. We identify and analyze here several morpholo-

gies and behavioural strategies toward this goal. The main contribution of this paper is to demonstrate that such *minimal cognition* (van Duijn et al., 2006) can collectively evolve in a multiagent system. We also suggest that it could be the first step toward more advanced cognitive abilities (Wróbel, 2012). Another novelty is a simplification of the artificial physics: instead of keeping a different set of environmental conditions for the developmental phase and the behavioural phase, we adopt the same physical rules for both.

## Controlling the development and behaviour of multicellular soft-bodied animats

The model used in this paper builds upon our previous work on soft-bodied multicellular animats (Joachimczak et al., 2012; Joachimczak and Wróbel, 2012). As before, the gene regulatory networks that control the bodies are encoded in linear genomes. We provide here only a brief summary of how the encoding works and how the dynamics of the network is simulated, then we describe in more detail two modifications that we brought to the system: unifying the physical conditions of the developmental and behavioral phases, and designing new cell-to-cell communication. In this new design, chemical signals diffuse between cells under a constraint of conservation of their total amount (in the previous implementation, mass was not conserved).

### Genome and gene regulatory network

The genome is represented by a list of genetic “elements” without fixed length. Genetic elements belong to three classes: (i) *genes*, which code for *products* (transcription factors or chemicals diffusing between cells), (ii) *regulatory elements*, and (iii) *special elements*, which encode inputs and outputs of the regulatory network. One or more regulatory elements form a regulatory region, which can be followed in the genome by one or more genes to make a *regulatory unit*. The activation levels of the regulatory elements of a unit influences the concentrations of products coded by this unit’s genes (Fig. 1). Conversely, regulatory elements are activated by the products currently present in the cell, which virtually “bind” to the genome with various probabilities (related to their concentration) and various affinities to the regulatory sites.

To simulate the behaviour of a cell, we first decode the genome to obtain the corresponding GRN, in which nodes represent regulatory units, and weighted directed edges represent relations of regulation. The signs of the weights indicate whether the regulation is excitatory or inhibitory, while the weights tune the chemical affinity between products and regulatory elements. The affinity also depends on the “distance” between two elements, calculated by construing each element as a point in an abstract 2D space of chemical interactions (not to be confused with the physical 2D space of the animat). The affinity is set to 0 if the distance is above a

Figure 1: Genome (left) and structure of a genetic element (right). Each element consists of a *type* field, which specifies its class (G: gene, P: regulatory, S: special), a *sign* field, and  $N$  abstract *coordinates* (here,  $N = 2$ ), which determine its affinity to other elements based on distance in  $\mathbb{R}^N$ .

certain threshold, and to a maximum value if the two points overlap.

While each cell in the animat body contains the same GRN, the product concentrations that encode the dynamic state of this network can be different from cell to cell. Concentrations are real values updated in discrete time steps. The increase in concentration, or “synthesis rate”, of a product  $P$  is influenced by the concentrations of products that have a non-zero affinity to the regulatory elements of the unit encoding  $P$ . The combined effect of all the products binding to the same regulatory element is additive; the combined effect of all the regulatory elements in a regulatory unit is also additive. If the net effect of the products that have an affinity to the regulatory elements of a regulatory unit is negative, the products encoded by this unit’s genes will decrease in concentration, or “degrade”. In addition, the products encoded by regulatory units degrade spontaneously.

The minimal concentration of a product is always 0, but the maximum concentration is different for transcriptional factors (1.0) and diffusive products (10.0). There are two reasons for this 10-fold difference. First, if the maximum concentration of diffusive products was low, it could not be detected in the cells far away from the source cell. Second, when the initial population is formed during simulated evolution (i.e. when the genomes are constructed randomly for the individuals in this population), elements that code for diffusive products are introduced in these genomes less often than elements that code for transcription factors. In contrast to our previous model, the products diffuse here in the body along the filaments that connect the cells (both during development and locomotion). At each time step, the fraction of concentration of a diffusive product transferred between cells is proportional to the difference of concentrations between these cells.

Diffusive products can be considered to be one form of an output produced by a cell (and input received by other cells). Our genome model also includes elements that encode GRN inputs coming from the environment and outputs representing cell actions. These *special elements* are not tied to regulatory units, the graph nodes to which they correspond do not have recurrent connections, and direct connections between input and output nodes are not allowed.

Input elements behave like other regulatory products (transcription factors and morphogens), but their concentration represents an environmental signal. In this paper we use five types of input elements, four of which can be seen as encoding “maternal morphogens”. Three of these morphogens diffuse during development from three point sources, so their perceived concentration in a given cell depends on the current position of this cell. One environmental signal is always present in the same concentration (1.0), throughout development and beyond, when the animat moves (this signal plays the same role as a bias node in artificial neural networks). The fifth chemical starts diffusing in the environment when the animat has finished developing, at which point the animat is supposed to move toward the source of this chemical. Its concentration in each cell depends on the cell’s distance from the source, and goes to 0 for a distance larger than 400 units (noting that the expected value from multiple trials of the initial distance from the center of mass of the animat to the food source is 300).

Whereas input elements encode products whose concentration is determined by the environment, output elements encode products whose concentration impacts the behaviour of the cells and the entire animat after development. In this study we use five output elements representing five possible cell actions: (i) division (when the concentration of the corresponding product crosses a threshold), (ii) rotation to the left and (iii) rotation to the right after division (cell orientation is represented by a vector; the rotation angle depends on the concentration of two products), (iv) contraction and (v) expansion of the filaments linked to the cell (the two products corresponding to these last actions are used only after development, when the mature body is able to move).

### Physics of cell interactions

As in our previous work, the animats are spring-mass systems in which cells correspond to point masses, and neighbouring cells are connected by filaments that act as weightless springs. This neighbourhood relation is determined by calculating the Gabriel graph (Gabriel and Sokal, 1969) of cell positions (Fig. 2).

In our model of two-dimensional swimming, taking after the simulation of undulatory robotic locomotion by Sfakiotakis and Tsakiris (2006), the fluid is stationary and only the spring-edges on the outline of the animat are subject to fluid drag. The force exerted on an edge of length  $L$  is the sum of a tangential component  $F_T = -d_T L v_T^2 \text{sign}(v_T)$  and a normal component  $F_N = -d_N L v_N^2 \text{sign}(v_N)$ , both proportional to the squares of the respective velocity components  $v_T$  and  $v_N$  via fluid drag coefficients  $d_N$  and  $d_T$  (where  $d_N = 200 d_T$ ).

**Soft bodies during development and locomotion** In contrast to our previous work, the rules of physics governing the development and locomotion are identical. These two

Figure 2: Example of the developmental mechanics (for individual #1, shown in Fig. 3). Cells are represented as circles of radius  $r$  and connected by springs with resting length  $2r$ .

phases remain separate, however, and are different in three respects. First, to prevent excessive forces and movements in the developing embryo due to cell division, cells are slowed down by an extra drag component proportional to the square of their velocity. This correction can be interpreted as the presence of an intracellular fluid more viscous than the external fluid (an alternative, not used here, would be to consider that immature filaments are less stiff). The second difference is that mature filaments in the adult body define polygons that act as pressurized chambers, whose expansion and contraction drive them out of equilibrium and generate a pressure force along the normal of each edge. Thus these chambers constitute a “hydrostatic skeleton” for the animat, which also prevents cells from passing through filaments. Finally, during development cells can break connections or form new ones (as if sprouting filaments or destroying them), whereas the connectivity in the locomoting adult remains fixed.

Formally, this means that the Gabriel graph is recalculated at every step of the development, and each pair of neighbouring cells is connected by a spring whose resting length is the sum of the cells’ radii (in the experiments described here, all cells have the same radius). When a cell produces a daughter cell through division, the new cell is placed closer than the sum of the radii, so the spring that connects these two cells pushes them away from each other, creating a cascading effect in the body. As the organism is growing, cells always attempt to maintain constant distances between them (Fig. 2), and new neighbourhood relations lead to the creation or removal of springs. To keep computational costs reasonable, we used a hard limit of 32 cells.

Once the development is finished, the filaments “mature” i.e. although they retain their elasticity and the body may change shape during movement, the pattern of connections between cells is no longer modified. The initial resting length  $L_0$  of each spring is set to the length it had at the last time step of development. From this point, each cell controls the springs connected to it using the products encoded by two output elements: one product for expansion and one for contraction. The concentrations of expansion

products  $e_1$  and  $e_2$  in the two cells connected by a spring, and the concentrations of contraction products  $c_1$  and  $c_2$  combine additively to modify the resting length according to  $L = (1 + A_{\max}(e_1 + e_2 - c_1 - c_2))L_0$ , where  $A_{\max}$  is a global parameter of the system representing the maximum actuation amplitude ( $A_{\max} = 0.2$  in this paper).

### Evaluation of behaviour and chemotaxis

In our evolutionary model, genetic operators can add elements (duplications), remove elements (deletions), or change the elements' type, sign, and coordinates (point mutations). The first two operations affect the size of the genome and the number of nodes and edges in the GRN, while the change of coordinates affects the affinities between products and regulatory elements. The genetic algorithm is generational, with population size 100, and tournament selection on five randomly drawn individuals. Five of the individuals in each generation are propagated without change to the next generation (elitism), and 20% undergo sexual reproduction (multipoint crossover). An evolutionary run stops when the fitness value is stable over a 500-generation span, which happened between generations #2000 and #3000 in the experiments described here. To accelerate evolution and evaluation, nonviable individuals are removed from the population, where an individual is deemed "viable" if three conditions are met: (i) there is a path between at least one input and the outputs associated with division, contractions or expansions in the GRN, (ii) no cell division happens during the last 100 time steps before the end of development (to allow the physics to equilibrate the adult structure; there is a fixed number of time steps for development), and (iii) the concentrations of expansion or contraction products vary during locomotion. These criteria of viability guide the search for the random genome that will be used to create the genomes of all the individuals in the initial population. These individuals are generated from the seed genome via the duplication, deletion and point mutation operators. The random search of a seed genome requires a few thousand trials.

### Fitness evaluation

After the soft body has fully developed, through cell divisions starting from a single cell, the animat begins to move. In our preliminary experiments we placed a food particle repeatedly at eight random locations forming a circle around the animat's center of mass, and gave higher fitness to animats closer on average to the particle (after a fixed number of time steps). Yet, the evolutionary search in this scenario was not very efficient: only about one third of the evolutionary runs resulted in "champions" that showed some chemotaxis abilities, but at a considerable computational cost due to the required eight test cases for each individual in each generation.

To improve the efficiency of the evolutionary search, we redesigned the fitness function to be composed of five terms

obtained by evaluating an individual in five test situations. (1) The first test situation assessed the ability to move as such: we measured the distance travelled in 10,000 simulation steps. This evaluation stage also allowed to determine the main axis of the animat and its preferred direction of movement. (2) Then, we placed a food particle on the animat's left, between  $-30^\circ$  and  $-90^\circ$  from the main axis, at a distance chosen uniformly and randomly in the range [200,400] from its center of mass (animats cover about 100 units along the main axis), and measured the remaining distance to the particle after 15,000 simulation steps or, if the animat's body overlapped with the particle earlier, the time it took. (3) The third test repeated the second: the state of the animat including its shape and the concentrations of products was reset to the state it had at the end of the first test, and the particle was placed again on the left. (4, 5) The last two tests were similar to tests (2, 3) with the particle placed on the right. The resulting fitness function (maximized by the genetic algorithm) was a linear combination of the distance  $d$  travelled in the first test (via a increasing reward), the remaining distances  $d_n$  from the animat's center of mass to the food particle, and the total durations  $t_n$  of the last four tests (via decreasing rewards):

$$f_{\text{fit}} = \frac{d}{c_m} + \sum_{n=1}^4 \left( 1 - \frac{d_n}{c_f} + s_r \left( 1 - \frac{t_n}{t_{\max}} \right) \right), \quad (1)$$

where  $c_f$  is the maximum distance at which a particle could be placed,  $t_{\max} = 15,000$  is the maximum number of steps in each test,  $s_r$  is the weight of the time reward with respect to the remaining distance reward (here,  $s_r = 4$ ), and  $1/c_m$  is the weight of the distance travelled with respect to the last four tests. This coefficient was set to a value such that, for an individual with efficient locomotion and chemotaxis, the first reward component was of the same order as each of the other four reward components. Our fitness function design promotes the evolution of a simpler behaviour first (here, locomotion), so that a more complex one (chemotaxis) can be built upon it. Considering the relations between learning and evolution, this design brings the fitness function close to a trainer or tutor that promotes gradual development of competences (by "scaffolding" or "shaping" the agent; (Wood et al., 1976; Dorigo and Colombetti, 1994)).

### Results: swimming patterns of four champions from independent evolutionary runs

An analysis of the champions obtained from multiple independent evolutionary runs ( $n = 40$ ) shows that about half of them were able to change direction and to head toward the food particle, while the other half could only swim forward. Our previous work (Joachimczak et al., 2012) had identified four classes of morphologies and styles of motor behavior that emerged more distinctly among the continuum of possible scenarios: symmetrical protrusions on the left

Figure 3: Patterns of cell activation (i.e. concentration of expansion minus contraction products) in individual #1 during one motion cycle while it performs a left (a) or right (b) turn. Red indicates expansion (positive activation); green: resting length; blue: contraction (negative activation). Numbers indicate time steps. The animat swims upward. and right (or “fins”), a protrusion at the end (or “tail”), undulation of the whole body, and alternation of whole-body pulsations, consisting of either fast expansion and slow contraction of bodies that had a pointy front and a blunt end, or the other way around (fast contraction with a blunt front). Strategies based on pulsations worked by exploiting the fact that fluid drag is proportional to velocity squared. It was also characterized by rapid swings of the concentration of expansion and contraction products in all cells at the same time, whereas in the first three strategies these concentrations varied in a sinusoidal fashion and exhibited phase gradients along the axes of the body. In the present work, it is the pulsation strategy that happened to be the most common among the champions who showed efficient chemotaxis—despite the fact that, in our previous work, individuals with protrusions were the fastest in forward motion. It is interesting to note that the other three strategies also tend to appear in the experiments reported here, but less clearly or only partially as components of a mix (see examples below). This is probably due to the different physics model and the new requirements for chemotactic abilities which could be encouraging pulsations over protrusions or undulation.

We chose four animats among the fittest to be analyzed in greater detail. The pulsation strategy is used by the first three, among which two have elongated bodies in the direction of motion. Individual #1 exhibits a sharp front and a blunt end, contracts slowly and expands quickly (Fig. 3). Individual #2 shows the opposite, with a blunt front and sharp end, contracting quickly and expanding slowly. It also generates thrust by wiggling a “tail” (Fig. 4). Individual #3 also uses a mixed strategy, generating thrust in part from a pul-

Figure 4: Patterns of cell activation (i.e. concentration of expansion minus contraction products) in individual #2 during one motion cycle while it performs a left (a) or right (b) turn. Red indicates expansion (positive activation); green: resting length; blue: contraction (negative activation). Numbers indicate time steps. The animat swims upward. Videos available at: <http://youtu.be/TS8Q0JfI7o0> and <http://youtu.be/Dw8-YCWodn8>

sating clump in the middle (by fast expansion and slow contraction) and in part by the movement of a small tail, too. A wave of contraction travelling from the front to the back moves this tail in a position perpendicular to the main axis of the animat (equal to the direction of motion) when the animat’s back expands, so that the tail pushes the animat forward (Fig. 5). Individual #4 is sharply different from the other three, as its body is elongated in the direction perpendicular to the main axis, and it moves by using two joined “fins”, which push backward in synchrony to generate a forward movement (Fig. 6). These fins expand when moving backward, and contract on their return. Their motion is induced by a wave of contractions travelling from the back toward the front.

In all four animats the control of chemotaxis performed correctly in the more general situation in which, after the animat reached one food particle, we placed another particle away from the animat without resetting its state to a pre-food situation (although the state was reset during the evaluation phase of the genetic algorithm). When turning toward the food, these four animats did not change their motion pattern, thus it is not immediately obvious how they performed the turn. Defining the level of “activation” of a cell to be the concentration difference between the expansion product and the contraction product, changes in collective activation patterns between the left and right turn can be observed in individuals #1 and #4, while this symmetry is much less clear in individuals #2 and #3 (Figs. 3-6).

To understand how the control of turning worked, we compared the average activation of each cell when food was placed in front of the animat to the activation of each cell when food was placed on the left or on the right. The experiments were performed as follows: (i) the animat was

Figure 5: Patterns of cell activation (i.e. concentration of expansion minus contraction products) in individual #3 during one motion cycle while it performs a left (a) or right (b) turn. Red indicates expansion (positive activation); green: resting length; blue: contraction (negative activation). Numbers indicate time steps. The animat swims upward. Videos available at: <http://youtu.be/-HoN7ZGU6W4> and <http://youtu.be/UZeCkWgeA5Q>

allowed to move forward without a particle for 10,000 steps and the direction of movement in the last 50 simulation steps was used to determine its main axis, then the average cell activity was calculated (over 5,000 steps in each case) with (ii) a food particle placed in the front, (iii) 60° to the left, and (iv) 60° to the right. The initial state of the animat (the product concentrations and body shape) in each case was identical to the state at the end of step (i).

Analysis of the changes in the average cell activation indicates that pulsating animats use different strategies based on changing the size of their body parts. Individual #1, the animat that contracts slowly and expands quickly, turns by contracting the part of its body closest to the food (Fig. 7a), as does individual #3, which uses a mixed strategy of pulsation and tail propelled by a wave of contractions (Fig. 7c). On the other hand, individual #2, which contracts quickly and expands slowly, turns by expanding the side opposite to food (Fig. 7b).

In terms of how forces generate motion, when individual #1 with a blunt end expands quickly, it pushes the blunt end against the fluid, and the relative increase in length of the external edges on the right side causes a push toward the left. On the contrary, when individual #2 with a pointy end contracts quickly, a relative increase in edge length on its right side leads to an additional pull toward the left. Although individuals #1-3 showed similar strategies for controlling turns, only in the case of the individual #1, which used a pure pulsation strategy, did we observe an immediate reaction of the cells (i.e. contraction of the springs, but maintaining their pulsation) to a food particle close to them. We also observed similar contractions for cells close to the

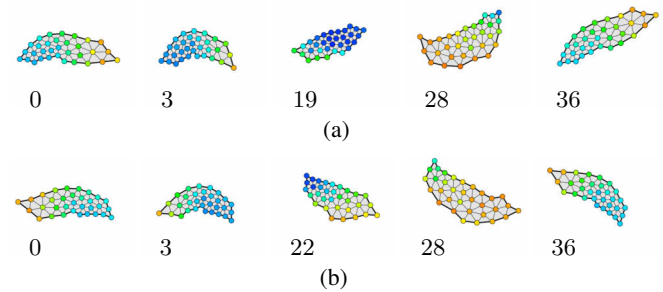

Figure 6: Patterns of cell activation (i.e. concentration of expansion minus contraction products) in individual #4 during one motion cycle while it performs a left (a) or right (b) turn. Red indicates expansion (positive activation); green: resting length; blue: contraction (negative activation). Numbers indicate time steps. The animat swims upward. Video available at: <http://youtu.be/rvM2T8gpDnU>

particle when it was placed inside the body, although this was not experienced during evolution.

In comparison to the first three examples of animats, all propelled by pulsations, individual #4 using two joined fins can turn and move significantly faster, sometimes even overshooting the target but correcting its trajectory afterwards. It is able to switch the direction of the wave of contractions: without food, the wave moves from the back to the front; with a food particle on the right, it moves from the right tip to the left tip, and vice-versa (Fig. 7d). During the switch, the animat maintains the overall motion pattern: the contraction waves are synchronized so that when the right half of the body moves backward, this part contracts. This results in a lower thrust from the right fin, hence a right turn, which is captured by the analysis of average cell activation.

Because the chemical diffusing from the food particle is sensed by all the cells, it is conceivable that the gene network is reacting proportionally to the strength of the incoming signal, and using this direct response to stimulate the turn. To detect this possibility, we computed the Spearman's rank correlation coefficient between the activity (expansion and contraction) of the cells and the distance to the food, i.e. strength of the diffusive signal (Fig. 8). The largest correlations can be observed in individual #1, the pulsating animat that expands quickly. During this animat's behaviour, the high correlations vary in regular patterns. This indicates that cells close to the food expand their springs and cells far from food contract their springs proportionally to the food signal. A similar pattern can often be seen, although not as clearly, in the other two pulsating animats, #2 and #3. This is not, however, the case for the two-finned individual #4. In its case, correlations between activity and distance are relatively low and unstructured, which suggests a more complex strategy during behaviour, including a substantial role played by intercellular communication.

Figure 7: Change in average cell activation (i.e. concentration of expansion minus contraction products) when moving a food particle from the left or right side to the front of an individual. White cell: no change; blue: average activation is lower; red: higher. The four pairs from (a) to (d) correspond respectively to individuals #1 to #4. All animats shown moving upward.

Figure 8: Variations of the Spearman correlation between cell activity and distance to food. Three curves are shown for individuals #1 and #4. They represent the correlation between cell activity  $X$  and the cells' absolute distance to food, where  $X$  stands for the cells' expansion (in red), their contraction (in blue), and their activity (expansion minus contraction, in black). The total period (60 to 70 time steps) corresponds to an animat turning left and moving toward the food. Values near 0 mean no correlation; values near +1 and -1 mean high correlations, which indicate here a direct relationship between the cells' behaviour and their distance to the food.

### Summary, perspective, and future work

In this work, we showed that it was possible for an evolutionary process to successfully produce soft-bodied multicellular animats that can forage for resources in their environment, and whose embryonic development and adult behaviour are both controlled by the same gene regulatory network. Neither a particular morphology nor a particular type of control were enforced, but different strategies were discovered by evolution starting from random genomes. The chemotactic behaviour that emerged from the interplay between the shape of the body and the local responses of differentiated cells, in the absence of any central control, can also be regarded as “minimally cognitive”.

The simulated evolution of a coordinated collective behaviour, where multiple agents are driven by the same distributed controller, provides a way to explore the space of possible morphologies and efficient modes of control in the nascent field of soft-bodied robotics. Our results show that soft robots are able to navigate efficiently and robustly by pulsing the body (symmetrically along the main axis) and expanding their left or right side slightly more in order to turn. We hope that these results can contribute to providing a source of inspiration for the development of new materials and actuators for soft robots.

Before such materials and actuators are available, however, much work can still be accomplished in virtual environments. As future work, we plan to investigate more thoroughly the types of motion and the nature of communication and synchronization among the cells of evolved individuals. In particular, we want to analyze how intercellular communication works to achieve efficient behaviour by exploring a scenario where only a subset of cells (for example, the cells on the surface) can sense the environment, while the rest of the body must rely on indirect information passed through diffusive substances. We would also like to better assess the benefits of distributed control, especially in terms of robustness to damage (e.g. malfunction of springs or cells) and resistance to external disturbances (e.g. distractors and noise).

## Abstract

This paper introduces StaCo: Stackelberg-based Coverage approach for nonconvex environments. This approach structurally differs from existing methods to cover a nonconvex environment, as it is based on a game-theoretic concept of Stackelberg games. Our key assumption is that one robot can predict (short-term) behavior of other robots. No direct communication takes place among the robots, the approach is decentralized. However, the leading robot can direct the system into the optimal setting much more efficiently just by changing its own position. This paper extends our previous work in which we have introduced the StaCo approach for coverage of a convex environment, with a simpler type of robots. We provide theoretical foundations of the approach. We demonstrate its benefits by means of case studies (using the Sim.Iam software). We show situations in which the StaCo approach outperforms the standard approach, which is based on combination of the Lloyd algorithm and path planning.

**Keywords:** Multi-robot coverage of nonconvex environments, Stackelberg games

## Introduction & Literature Overview

Multi-robot control in an unknown environment is an emerging topic of various research fields (e.g., flocking control (Olfati-Saber, 2006), aggregation (Martinoli et al., 1999), multi-robot coverage (Cortes et al., 2004), formation (Ren and Sorensen, 2008)). This paper focuses on multi-robot coverage.

Most of the proposed solution methods for multi-robot coverage are not applicable in practice, as they encounter difficulties such as failing to find the globally optimal solutions and the inability to account for nonconvex environments (Cortes et al., 2004; Martinoli et al., 1999). As a consequence, despite the wide range of existing works in the domain of multi-robot coverage (Breitenmoser et al., 2010; Butler and Rus, 2004; Cortes et al., 2004; Pimenta et al., 2009; Ranjbar-Sahraei et al., 2012; Schwager et al., 2009), there are still only very few in-field deployments.

Some works dealing with control of the system of multiple robots (not necessarily with multi-robot coverage) have tried to tackle the critical issues of nonconvexity and failing to find the global optimum. Ganguli et al. (2007) solve the distributed Art Gallery Problem in a nonconvex environment. In (Ganguli et al., 2009) the problem of the coordination of a group of robots to achieve rendezvous in a non-

convex environment is treated. An optimal control method to drive a team of multiple robots to target sets under collision avoidance and with proximity constraints in a known environment with obstacles is introduced in (Ayanian and Cumar, 2008). An elegant way of tackling the problem of nonconvex environments is introduced in (Caicedo and Žefran, 2008a,b). The nonconvex region is first transformed by a diffeomorphism to a convex region. Subsequently, the standard Voronoi coverage approach is applied on this region. As the authors themselves state, there is one major drawback of this method: The first phase of this method (transforming the region into a convex region) is computationally very expensive. Moreover, in some cases the solution of the transformed problems does not correspond to the solution of the original problem. Pimenta et al. (2008) apply the geodesic distance measure to Voronoi coverage. While this method is very efficient for some types of environments, it is not guaranteed that the optimal solution will be found for all types of nonconvex regions even if this solution is reachable.

One of the most practically applicable approaches for coverage of a nonconvex environment is introduced in (Breitenmoser et al., 2010). This algorithm combines the standard Lloyd algorithm with a local path planning. However, while this algorithm converges to the locally optimal configuration, it might be extremely slow and does not resolve the issues regarding failure to find the globally optimal configuration.

While the performance of the above mentioned algorithms might be improved via more effective algorithmic implementation, fundamental improvements of the settling time and convergence could be made if the structure of the robotic swarm played a role. Motivated by this idea, this paper introduces a game-theoretic approach which can deal with nonconvexity and local optimality issues more efficiently than the existing algorithms. The Stackelberg Coverage (StaCo) approach is based on the game-theoretic concept of Stackelberg games (Staňková, 2009; Staňková et al., 2013). It assumes that one robot is more advanced than the others. This more advanced robot, called a leader, perceives the environment globally. By its own movement, the leader changes the boundaries of the Voronoi regions of the other robots. Subsequently, and without any direct communica-

tion with the other robots, the leader steers the other robots into a more optimal configuration. The main advantage of the StaCo approach is keeping the benefits of decentralized methods while performing almost as well as the centralized methods with respect to the system optimality; it preserves the simplicity of the major population of the robotic swarm, while one robot can predict behavior of the others and act so that the desired behavior is achieved faster and with a higher precision.

This paper extends the results of (Staňková et al., 2013), where we introduced the StaCo approach for multi-robot coverage of convex environments, toward multi-robot coverage in nonconvex environments. Moreover, more realistic robots are considered in the case studies.

Game theory has been successfully applied in various fields; its known applications in the robotic field relate to pursuit-evasion and search problems (Meng, 2008; Raboin et al., 2010). However, application of the Stackelberg games in the multi-robot coverage of nonconvex environments is new.

In the next sections, we will briefly summarize our previous work and introduce the problem of the Voronoi coverage of a nonconvex environment and its properties. Subsequently, we will explain the StaCo approach in nonconvex coverage and analyze its properties. We will also present case studies in which we demonstrate the advantages of the StaCo approach. We will conclude by discussing the achieved results, limitations of the proposed approach, and the future research directions.

### StaCo in Convex Environments

In (Staňková et al., 2013) we have introduced the StaCo approach for convex environments, as a specific case of a Stackelberg game with one leader (more advanced robot) and multiple followers (very simple robots). We have shown theoretically and by means of case studies that the proposed approach can never perform worse than the standard coverage algorithms, such as the Lloyd algorithm (Cortes et al., 2004), while most of the time the StaCo approach significantly outperforms the standard approaches (by the means of settling time or by finding the globally optimal configuration when standard approaches fail). Figure 1 from (Staňková et al., 2013), illustrates the performance of the StaCo approach in comparison to the classical coverage proposed by Cortes et al. (2004). All experiments are carried out in convex environments and with robotic swarms of different sizes.

### Voronoi Coverage of a Nonconvex Environment

In this section we will informally discuss the problem of nonconvex environment coverage, including a discussion on the existence and the uniqueness of the optimal Voronoi configuration, and uniqueness of this optimal solution.

#### Problem Formulation

The goal is to deploy a group of networked robots in a nonconvex environment, i.e., an environment including

Figure 1: Comparison of the coverage settling time between the proposed StaCo approach and the classical coverage approach for robotic swarms of different sizes in convex environments (Staňková et al., 2013).

free standing obstacles, holes, and/or areas with nonconvex boundaries.

### Problem Properties

**Existence of the optimal Voronoi configuration:** Unlike in a convex environment, the optimal solution does not necessarily exist in a nonconvex environment. This is caused by the fact that the centroids of Voronoi regions are computed in the convex environment, not taking any obstacles into account. However, the centroid of the region might lie on an obstacle or be part of an unreachable region, as shown in Figure 2a. Considering only the situations in which the centroids of the optimally chosen Voronoi regions are reachable, the globally optimal solution exists (but may be impossible to find with standard algorithms).

**Uniqueness of the optimal Voronoi configuration:** The solution configuration does not need to be unique, as there might be multiple solution configurations that are permutations of each other. See Figure 2b for an example of a circular region with a circular obstacle in the middle. Independent of how many multiple robots would be placed in this region, there exist infinitely many optimal Voronoi tessellations in this region.

### StaCo Voronoi Coverage of a Nonconvex Environment

#### Theoretical Foundation & Properties

In this section we formulate multi-robot coverage problem in a nonconvex environment as a dynamic Stackelberg game with one leader and multiple followers, with additional assumptions on the robot's obstacle avoidance behavior. The approach proposed in this section will be referred to as StaCo: Stackelberg-based Coverage Approach. For more details on Stackelberg-based Coverage of convex environments, see (Staňková et al., 2013).

Figure 2: Properties of the Voronoi coverage of a nonconvex environment: (a) Example of the region an obstacle in which the optimal configuration is unreachable. The crosses denote the optimal positions of the robots. (b) Example of a region with (infinitely) many optimal Voronoi tessellations.

Let  $\Omega \subset \mathbb{R}^2$  be a convex region. Let  $n$  convex obstacles  $o_1, \dots, o_n$  be placed in  $\Omega$ . Let us consider  $M$  robots (players) placed in the region at time  $t = 0$  in  $\Omega \setminus \{\bigcup_{j=1}^n o_j\}$ .

One of the players, denoted for the sake of simplicity as player 1, is the *leader*, all other players, denoted by 2,  $\dots$ ,  $M$ , are the *followers*. The roles of the players are assumed to be fixed during the entire duration of the game.

Let  $\mathbf{x}(t) \stackrel{\text{def}}{=} \{x_1(t), x_2(t), \dots, x_M(t)\}$  be the configuration of the robots at time  $t$ , with  $t \in [0, T]$ ,  $\mathbf{x}(0) = \{x_1(0), x_2(0), \dots, x_M(0)\}$  being the initial configuration of the robots and  $\mathbf{x}(T) = \{x_1(T), x_2(T), \dots, x_M(T)\}$  being their final configuration at final time  $T$ , with  $x_i(t) \neq x_j(t)$  if  $i \neq j$ . Note that  $x_i(t) \in \mathbb{R}^2$  for each  $i \in \{1, \dots, M\}$ . Let  $V_i(t)$  indicate the Voronoi region (cell) in which  $i$ -th robot is located at time  $t$ . For each  $\mathbf{x}(t)$  the Voronoi regions are defined by the *Voronoi partition* of  $\Omega$  at time  $t$ ,  $\mathcal{V}(t) = \{V_1(t), \dots, V_M(t)\}$ , generated by the points  $\mathbf{x}(t) = (x_1(t), \dots, x_M(t)) : V_i(t) = \{\omega \in \Omega : \|\omega - x_i(t)\| \leq \|\omega - x_j(t)\|, \forall j \neq i\}$ . System dynamics are given by the following system of ordinary differential equations:

$$\dot{x}_i(t) = u_i(t), \quad i = 1, \dots, M \quad (1)$$

where  $u_i(t) \in \mathbb{R}^2$  is the control (decision) of the  $i$ -th robot at time  $t$ . The cost functions for the leader (robot 1) at time  $t$  is given by

$$C_1(t) = \sum_{i \in \{1, \dots, M\}} \int_{V_i(t)} \|\omega - x_i(t)\|^2 d\omega. \quad (2)$$

Let us assume from now on that  $T$  is defined as the so-called stopping time, i.e., the minimal time such that for each  $\tau > T$  the cost  $C_1(\tau)$  does not change:  $T = \min\{\nu : C_1(\tau) = C_1(\nu) \forall \tau > \nu\}$ . Then the leader minimizes  $C_1(T)$ . Alternatively, the leader might minimize  $T$ . The cost function for the follower  $j \in \{2, \dots, M\}$  at time  $t$  is

$$C_j(t) = \int_{V_j(t)} \|\omega - x_j(t)\|^2 d\omega. \quad (3)$$

The problem of the leader (robot 1) can be then defined as

$$(P_{\text{StaCo}}) \begin{cases} \text{Find } u_1^{(S)}(\cdot) = \arg \min_{u_1(\cdot)} C_1(T), \text{ w.r.t.} \\ u_j(\cdot) = \arg \min_{u_j(\cdot)} \int_{V_j(t)} \|\omega - x_j(t)\|^2 d\omega. \\ \dot{x}_i(t) = u_i(t), \end{cases}$$

with  $j = 2, \dots, N$ ,  $i = 1, \dots, N$ . Note that in a nonconvex case,  $u_1^{(S)}$  involves both obstacle avoidance and reaching the goal behavior. Therefore, the underlying assumption here is that obstacle avoidance is one of the possible controls in (1). Moreover, we want to see how quickly the optimal Voronoi tessellation is found, i.e., the secondary goal is to minimize  $T$ .

**Proposition 1.** *Let at time  $t$  each player  $i$  know only state  $x_i(t)$  and corresponding  $V_i(t)$  and let Hessian of (2) be positive definite at each  $t$ . Then the so-called continuous-time Lloyd descent (Cortes et al., 2004)*

$$u_i^*(t) = \kappa \left( \frac{\int_{V_i(t)} \mathbf{x} d x_i}{\int_{V_i(t)} d x_i} - x_i(t) \right), \quad (4)$$

$\kappa > 0$ , extended by the standard path planning algorithm for obstacle avoidance (Breitenmoser et al., 2010), asymptotically converges to minimal  $C_1(T)$  and to minimal  $C_j(T)$  for  $j = 2, \dots, M$ , provided that the final configuration in which the minimal  $C_1(T)$  is reachable (i.e., no optimal  $x_i$  lies on an obstacle or in an unreachable region).

*Proof.* As shown in (Cortes et al., 2004),  $u_i^*(t)$  defined by (4) with respect to  $\dot{z}_i(t) = u_i(t)$  converges asymptotically to the set of critical points of (2). The critical points of (2) coincide with critical points of (3). If corresponding  $V_i$  is finite, this solution is global due to positive definiteness of (2), as follows from (Du et al., 1999). Assuming that the obstacle avoidance is one of the possible moves in (1) for each robot and that the optimal configuration is reachable from the initial configuration, this concludes the proof.  $\square$

Validation of the positive definiteness of (2) is an open problem (Cortes et al., 2004) and even if the convergence to the global optimum is guaranteed, in general no guarantees on the speed of this convergence exist. This leads us to the question whether there exist algorithms that perform better than the standard Lloyd algorithm (combined with the obstacle avoidance (Breitenmoser et al., 2010) as the covered environment is nonconvex) if we allow the leader (robot 1) to have more information about the state and decisions of the followers.

Note that while a certain position might be unreachable using the classical Lloyd algorithm (a robot might, for example, get stuck on an obstacle, while the Lloyd algorithm would lead the robot to continue through the obstacle), it might be reachable using combination of the Lloyd algorithm and path planning (Breitenmoser et al., 2010). In the reminder of the article, we will refer to the combination of the the Lloyd algorithm and a path planner for obstacle avoidance as the *standard approach*, assuming tacitly that

the StaCo approach uses the same obstacle avoidance mechanisms as the standard approach.

The solution of  $(P_{\text{StaCo}})$  strongly depends on the so-called information pattern, i.e., the amount of information that each player knows and recalls over her own state, the state of the others, and action made by herself and the others during the game (Başar and Olsder, 1999; Staňková and De Schutter, 2011; Staňková et al., 2013). If at each time  $t \in [0, T]$  robot  $P_1$  knows only  $\mathbf{x}(t)$ , the standard approach and the Stackelberg approach might coincide (unless more locally optimal solutions exist). However, if  $P_1$  has more information available, the StaCo approach will perform better than the standard approach (Staňková et al., 2013). The following proposition extends Proposition IV.1. in (Staňková et al., 2013).

**Proposition 2.** *Let player 1 know  $x_j(\tau)$  and  $u_j(\tau)$  (for all  $j \neq 1$ ) for  $\tau \in [t, t + \Delta]$ , with  $\Delta > 0$ , where  $u_j(t)$  is defined by (4). Let  $u_1^{(S)}(t)$  denote the optimal control of player 1, possibly dependent on  $u_j(\tau)$ ,  $\tau \in [t, t + \Delta]$ . Let  $T^{(S)}$ , and  $C_1^{(S)}(T^{(S)})$  denote the corresponding stopping time and the final payoff for player 1 in such a situation, respectively. Then  $C_1^{(S)}(T^{(S)}) \leq C_1^{(L)}(T^{(L)})$ , where  $C_1^{(L)}$  and  $T^{(L)}$  denote the cost of the player 1 if the classical approach, combining the Lloyd algorithm and a path planning, is adopted and the corresponding stopping time, respectively. This inequality holds if the optimal final configuration  $\mathbf{x}(T)$  is reachable from the initial configuration  $\mathbf{x}(0)$ . Moreover, if  $C_1^{(S)}(T^{(S)}) = C_1(T^{(L)})$ , then  $T^{(S)} \leq T^{(L)}$ .*

*Proof.* The leader's decision is not bound by any restrictions. If all past configurations of the StaCo approach and the Lloyd approach coincide, setting the leader's decision to (4) leads to  $T^{(S)} = T^{(L)}$ ,  $C_1^{(S)}(T^{(S)}) = C_1(T^{(L)})$ . Note that the Hessian of (2) might not be positive definite with the leader's decision defined by (4). Thus,  $u_1^{(S)}(t)$  either coincides with (4) when the standard approach is adopted, or, if this choice would lead to only sub-optimal solution,  $u_1^{(S)}(t)$  differs from (4) and leads to a better outcome. This outcome readily follows from Proposition IV.3. in (Staňková et al., 2013).  $\square$

Giving more information to the leader almost always leads to a better outcome for the leader also in a very general setting (Başar and Olsder, 1999; Staňková, 2009), while the StaCo approach never leads to an outcome worse than that reached by standard methods (Cortes et al., 2004; Staňková et al., 2013). This follows from the fact that the classical Lloyd algorithm in which there is no hierarchy among the robots is a special case of the StaCo approach in which the leader does not predict possible position of the other robots and optimizes only locally. Should this behavior be optimal, it would also be adapted by the leader in the StaCo approach.

## Implementation

Following the theoretical description provided in the previous section, in this section we will explain implementation

of the StaCo approach for coverage of nonconvex environments.

In StaCo, the leading robot (we assume that this robot is only one, while keeping in mind that the StaCo approach allows for multiple leaders) has a higher computational capability and more information than the following robots. Subsequently, the overall performance of the system is improved, and the StaCo approach can reach the optimal configuration faster than classical coverage approaches. Moreover, the StaCo approach can also reach the global configuration even if the standard approach fails.

The proposed StaCo approach for nonconvex environments combines three different components. The first one is the Lloyd algorithm, which is already used in the classical Voronoi-based coverage approach (e.g., by Cortes et al. (2004)), and has been mentioned also in the previous section. The second component is the Stackelberg game (described in the previous work of the authors (Staňková et al., 2013)). The third component is a local path planner, including object avoidance and wall following behaviors. This component helps the robot to pass nonconvexities (e.g., obstacles) and move efficiently toward its goal.

**Decision making of leading and following robots:** The leader's prediction of the possible future behavior of other robots and enforcing their optimal behavior via the leader's own movements (without a direct communication) are the main ideas behind StaCo.

The followers follow the simple rules of Lloyd algorithms, as shown in Figure 3a. Each follower continuously computes its Voronoi region center, sets this center as its goal, and tries to reach it, where the goal is a particular point in the 2D-space. Computing the Voronoi center can be done both via having access to global coordination of other robots, or via local communication as proposed by Cortes et al. (2004).

The decision making for the leader is more complex. The leader computes its own movement trajectory efficiently directing the entire group to the best possible configuration. Theoretically, this can be achieved by finding the explicit solution of  $P_{\text{StaCo}}$ , introduced in previous section. However, computation of such a solution analytically is very complicated and therefore, we compute the approximate solution of  $P_{\text{StaCo}}$  in a numerical way. In this numerical computation, the leader predicts possible behavior of the other robots as a response to its own behavior only for a fixed time interval and fixed number of directions for the leader's next move. The direction which implies the minimal cost function value is chosen as the immediate leader's goal. The immediate goal will be updated by the same procedure after the a priori fixed time. The sequence of such short-term goals defines the leader's movement trajectory. See Figure 3b for the scheme of the leader's behavior.

**Remark 3.** Note that the leader's prediction quality is directly influenced by the type and amount of information that is available to the leader. In our experiments, it is assumed that the leader knows the position of other robots and knows their dynamics. Additionally, the leader knows the map of

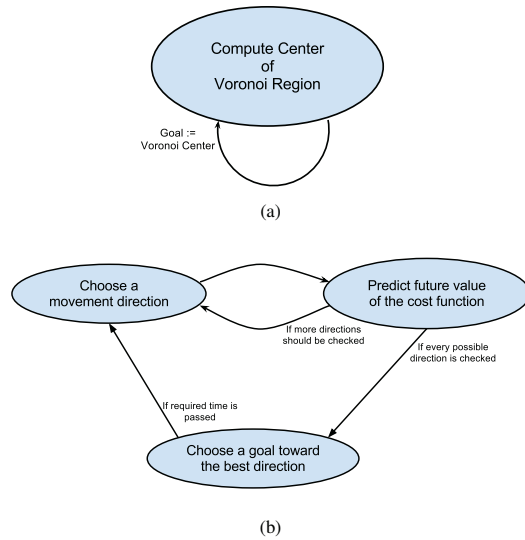

Figure 3: Scheme of robot behaviors/decisions: (a) simple behavior of a follower robot, in which the goal is a specific location in 2D space that the robot tries to reach using a local path planner. (b) the decision making of a leader robot in which the leader figures out which movement direction concludes to the best overall performance of the group.

the environment (more precisely, the position of obstacles). As long as only one robot or a very few number of robots has these abilities among a large number of simple robots, we can consider these assumptions as being practical and feasible, especially due to high capabilities of most modern robots.

**Remark 4.** Solving the  $P_{StaCo}$  problem in a numerical way can be improved in different aspects. First of all, the more movement directions the leader considers, the more accurate the movement, and the higher efficiency. Any metaheuristic which helps the robot in finding the best movement direction can be incorporated into the proposed approach. For example, with use of the A\* search algorithm one can penalize choosing a trajectory passing very close to the obstacles, as opposed to an obstacle-free trajectory. Many other search heuristics (e.g., GA and Simulated Annealing) can be used to find the best movement directions in the fast and accurate manner (Resende and de Sousa, 2004). However, study of these techniques is beyond the main scope of this paper, which focuses on overall applicability and efficiency of StaCo.

**Local path planner design:** Local path planner has an important role in adapting the StaCo approach for convex environment, proposed in previous work of the authors (Stařková et al., 2013), to coverage of nonconvex environments. Different local path planners are available for autonomous robots (Buniyamin et al., 2011). In (Breitenmoser et al., 2010) the *TangentBug* planner was used to tackle environment nonconvexities. In this paper, we use the hybrid controller proposed by Egerstedt (2000), in which robots follow three basic behaviors of *go-to-goal*, *avoid-obstacle*,

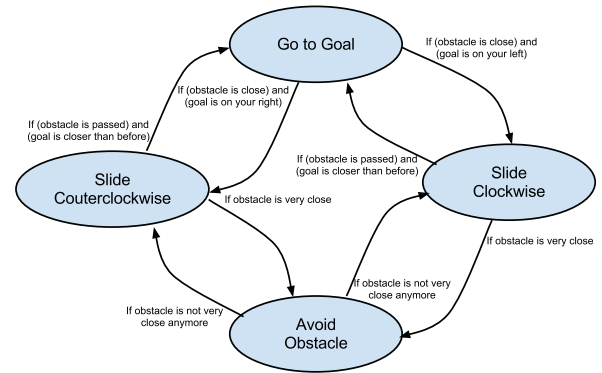

Figure 4: Hybrid automata used as local path planner designed for local path planning in nonconvex environments.

and *sliding along walls*. The hybrid automaton for this behavior-based path planner is shown in Figure 4, where the transitions and resetting values are explained qualitatively. We have adopted this path planner, as it is widely used by other robotic researchers, due to its simplicity of implementation, its robustness to environment changes, and its efficiency in finding the best available trajectory avoiding the obstacles of different shapes. Interested readers are referred to (Egerstedt, 2000) for more details on the design of this local path planner.

While the robot is moving toward its goal (i.e., Voronoi region center), if an obstacle appears in its way, the robot slides on the surface of the obstacle, until it gets to a position from which the goal is closer than it was before detecting the obstacle (i.e., the obstacle is already passed), then it switches back to the standard goal following. If at some point the robot gets very close to the obstacle, a pure repulsive behavior emerges which avoids collision with the obstacle.

**Remark 5.** The hybrid controller used for local path planning is always able to pass obstacles and move toward the reachable goals (Egerstedt, 2000). However, when the goal is unreachable (i.e., inside of an obstacle or bounded by obstacles), the path planner keeps moving the robot along the borders of the obstacle. In this paper we let the robot move around the obstacle as far as it is required, which will make an average position closer to the goal. However, a useful alternative is to stop the robot after one full cycle around the obstacle, as proposed by Breitenmoser et al. (2010).

## Simulations

In this section, we will study the performance of the proposed StaCo approach in comparison to the classical Voronoi-based coverage approach in nonconvex environments introduced by Breitenmoser et al. (2010). Firstly, the simulation environment and the mobile robot platform will be introduced. Secondly, the efficiency of the StaCo approach compared to the classical approach will be illustrated in two case studies.

## Simulation Setting

For examining the performance of the proposed coverage approach, Sim.I.am, a MATLAB-based educational software developed by de la Croix and Egerstedt (2013), is used in different coverage scenarios. The mobile robot platform, which is implemented in Sim.I.am, is the Khepera III (K3). The K3 is equipped with 11 infrared (IR) range sensors, nine of which are located in a ring around the robot and two are located on the underside of the robot. The IR sensors are complemented by a set of five ultrasonic sensors.

In the previous work of the authors (Staňková et al., 2013) the simulations of the proposed approach were carried out with a group of mass-less robots (i.e., neither the dynamic nor the kinematic model of the real-world robots were considered). In contrast, in the new simulator the robots (the nonholonomic Khepera robots) are much more realistic. Therefore, compared to (Staňková et al., 2013) and vast majority of papers on the Voronoi coverage, simulations in this paper are much closer to the real-world scenarios.

In the simulation environment, we have access to the array of nine IR sensors that encompass the K3. IR range sensors are effective in the range  $0.02\text{ m}$  to  $0.2\text{ m}$  only. Since the K3 has a differential wheel drive, it has to be controlled by specifying the angular velocities of the right and left wheels ( $v_l, v_r$ ). Therefore, the conversion between a unicycle input, the forward and angular speeds, to differentially driven inputs are implemented based on following equation for the  $i$ th robot:

$$\begin{aligned} \dot{x}_i^1 &= R(v_l + v_r) \cos(\theta) \\ \dot{x}_i^2 &= R(v_l + v_r) \sin(\theta) \\ \dot{\theta}_i &= R(v_r - v_l)L \end{aligned} \quad (5)$$

where  $x_i^1$  and  $x_i^2$  denote coordination of the robot in horizontal and vertical directions,  $R$  is the radius of the wheels, and  $L$  is the distance between the wheels, which are known a priori. Wheel encoders are used to provide required information to the odometry of robot. The relevant information needed for odometry is the radius of the wheel, the distance between the wheels, and the number of ticks per full turn of the wheel, which are all implemented internally in the simulator. Note that the equations (5) extend equation (4) in which the robot is considered to have no mass and to be holonomic.

The embedded controller described previously in the form of a hybrid automaton (Figure 4) is used to deal with the local path planning tasks. The transition for moving from “go to goal” behavior to the “sliding mode” happens when a robot is in a distance less than 15 cm, and it will move to the pure repulsive behavior (i.e., obstacle avoidance) when the robot is closer than 6 cm to the obstacle.

The prediction time in which the leading robot finds the approximate best movement direction (Figure 3) is a period of 3 seconds and the robot calculates the final value for moving to 8 different directions (i.e., right, up-right, up, up-left, ..., down right) for this period of time. Note that the way in which the leading robot computes its next step agrees with

the concept of the model predictive control known from the optimal control theory literature (Mayne et al., 2000).

## Results

Efficient coverage behavior of StaCo in convex environments is reported in our previous work (Staňková et al., 2013): As shown in Figure 1, the StaCo approach outperforms the classical coverage approaches in most of the environmental settings, and in the worst case StaCo and classical techniques have equal performance.

We use two case studies to show the high performance of StaCo in coverage of nonconvex environments and simultaneously we compare the results with the approach proposed by Breitenmoser et al. (2010).

The two non-trivial case studies for examining the StaCo approach in nonconvex environments are illustrated in Figure 5. In both scenarios five robots are initiated at random positions. The obstacles make the environment nonconvex which consequently makes an efficient coverage difficult.

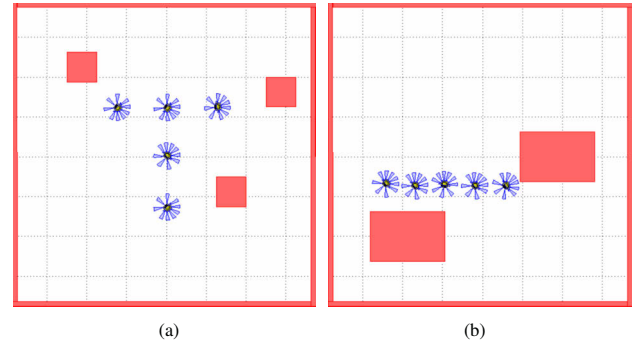

Figure 5: Initial settings for two experiments with five robots: (a) Scenario I. (b) Scenario II.

In both scenarios (Figures 5a and 5b), first the classical coverage approach for nonconvex environments is applied. In this approach, robots move toward their goals while a local path planner is used for obstacle avoidance and obstacle following purposes. Afterwards, we apply the StaCo approach to the same initial configurations, where one (randomly selected) robot acts as the leader. In Figure 5a, the robot in the center and in Figure 5b, the leftmost robot are the leaders. As explained earlier, the leader enforces its decisions on the other robots via its movements in the environment.

The coverage results of initial configurations shown in Figs. 5a and 5b are shown in Figures 6a-6c and Figures 6d-6e, respectively. Firstly, the robot trajectories for both classical coverage and StaCo approaches are shown (Figures 6a and 6d). Subsequently, the final configuration and the final Voronoi tessellation for each approach is illustrated (Figures 6b and 6e). Finally, the cost functions (2) for both approaches are plotted in Figures 6c-6f with respect to time.

As shown in Figures 6c and 6f, the StaCo approach finds the optimal configuration in a short time, while the classical approach is unable to find this optimal configuration

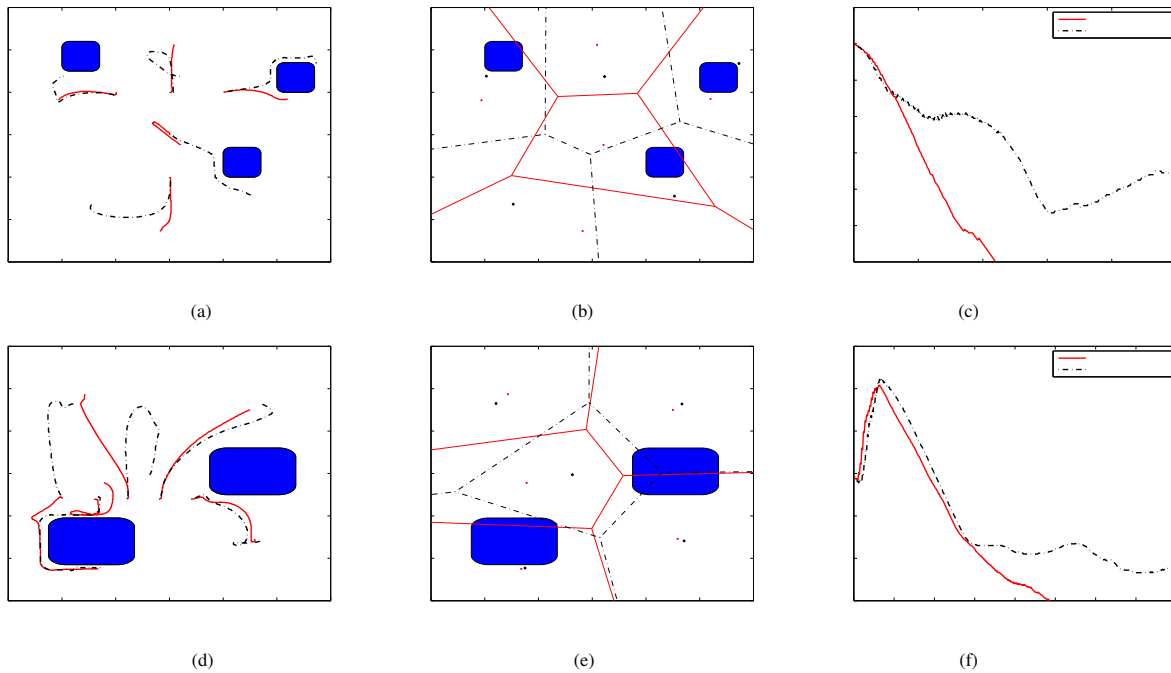

Figure 6: Experimental comparison between classical coverage approach (dash-dotted line) and StaCo approach (continuous line): (a) robot trajectories for Scenario I. (b) final robot configurations and final Voronoi tessellations for Scenario I. (c) cost function comparison for Scenario I. (d) robot trajectories for Scenario II. (e) final robot configurations and final Voronoi tessellations for for Scenario II. (f) cost function comparison for Scenario II.

even in the long term. From the trajectories of the individual robots (Figures 6a and 6d) it can be seen that while the classical approach moves the robots toward the optimal positions blindly (they can not predict whether obstacles will cause problems or not), in the StaCo approach, the leader which has access to more information and higher computation abilities, can enforce the entire group to move to the optimal configuration more efficiently.

### Discussion, Conclusions & Future Research

In this paper we have shown the high potential of the StaCo approach in the coverage of a nonconvex environment. In the situations in which the leader can predict the long-term behavior of the other robots, the StaCo approach outperforms the standard approaches for coverage of nonconvex environments. Moreover, we have shown that the StaCo approach outperforms the standard approaches even if the prediction capabilities of the leading robot are very limited. Extending the leader's prediction horizon will then lead to even better results. The main advantage of StaCo compared to any possible centralised coverage approach, is that StaCo does not rely on any direct communication between robots.

Leader's predictions might become computationally expensive especially in an environment with many obstacles and/or if the robotic swarm is very large. More advanced optimization methods might then have to be applied to overcome this possible drawback. Our next research step is to address this issue.

Moreover, we plan to implement StaCo in a real-robot setting using a combination of TurtleBots as the leaders and e-pucks as the followers. Although we do not expect implementation problems due to the available advanced robots, we need to explore in detail the level of StaCo precision that can be achieved in in-field scenarios that have different environmental and technical conditions.

Last but not least, our future research will include expressing the optimal leader's behavior in explicit form and extending the number of leaders (in such a case the hierarchy between the individual leaders might play a role).

# Simulating Limited Diversity in Evolution of Influenza

Takahiro Sasaki

Sony Computer Science Laboratories, Tokyo, Japan  
sasaki@csl.sony.co.jp

## Abstract

In many cases, analyses on infectious diseases focus on how the epidemic arises, spreads, and whether diminishes or gets fixated among host populations under particular conditions, without taking the evolutionary perspective into account. With some infectious diseases, however, the pathogens themselves evolve comparatively rapidly during the time course, so that the co-evolutionary dynamics among hosts and pathogens should be considered at the same time. In this paper, we focus on influenza and propose a bilayered, multi-agent-based simulation that combines an epidemic model and a viral evolution model. The latter model includes genomic segments of the viruses whose evolutionary paths are guided by two selective pressures; one originates from the viral-host immune interaction and the other originates from intra-genomic constraints within the virus. By including such a micro-level representation in the model, we show mechanisms that generate the limited diversity of viruses, which is a fundamental yet unexplained temporal characteristic observed in the evolution of influenza. The full version of this work has already been published in (Sasaki, 2013).

## Introduction: Limited Diversity

While influenza is a quite common infectious disease, the pattern of its global circulation and evolutionary dynamics still pose many questions to be answered (Nelson and Holmes, 2007). *Limited diversity* observed in the viral evolution of influenza is the one that has not been fully investigated. Influenza viruses have single-stranded RNA, which lacks an error correction mechanism and thus results in the high mutation rate of the genome. Thus, while continual changes accumulate in the viruses as time passes, there is always a chance for a new genetic lineage to diverge, which could theoretically result in ever-increasing explosive diversity. However, in reality, the diversity of the existing viruses is relatively limited to a certain extent at the population level and at any particular point in time. On one hand, this evolutionary behavior is in practice an important matter to be considered when we make effective plans and take medical action for minimizing the negative impact of infectious diseases, while on the other hand, it purely engages our inquisitive minds and makes us think about what causes the emergence of limited diversity in influenza viruses.

For example, Ferguson et al. (2003) discussed the role of short-lived non-specific cross-immunity as a possible mechanism that limits viral diversity. However, the biological mechanisms or evidence that actually support it have not necessarily been fully shown. By adding a more precise micro-level representation of viral evolution to the model, we propose another mechanism that also generates the limited diversity with more natural explanation than the previous work.

## Methods: Model

We propose a bilayered multi-agent-based model that consists of an epidemic circulation layer and a viral evolution layer. As in typical epidemic simulations, each member of the host population is individually represented as a virtual agent (Eubank et al., 2004; Parker, 2007; Epstein, 2009). The viruses, also represented as agents, are replicated and circulated among the hosts with their genomes evolving.

Reflecting the fact that the genome of the real influenza virus is composed of eight distinct but possibly interrelated segments, we represent our pseudo virus as a composite of multiple strings instead of treating it as just a monolithic component like most of the previous studies have done. In our model, for simplification we just consider two strings. The first, string  $g$ , determines the epitope recognized by the immune systems of the hosts, and the other, string  $r$ , does not directly interact with the immune systems but mutually regulates the evolution of  $g$  and of itself.

The key and unique point of our model is that the evolution of viruses is driven and/or regulated by two distinct selective pressures (Fig. 1). On one side, string  $g$  is subjected to repulsive pressure because immune systems prevent hosts from being infected repeatedly by viruses with the same genomic configuration. Thus,  $p_1$ , a component of viral fitness derived from the repulsive pressure, can be represented as a monotonic increasing (possibly sigmoidal) function of  $d_i$ , the distance between the binary pattern of  $g$  and the binary pattern of those held in immune memory. On the other side, however,  $g$  is subjected to attractive pressure because of intra-genomic constraints. Even though the viral genome

Figure 1: Micro-model of viral evolution

is separated into several segments, none of these segments can evolve totally independently from the others but a certain degree of consistency among them must be held to keep viral functions effective (Rambaut et al., 2008). Thus,  $p_2$ , another component of viral fitness derived from the attractive pressure, can be represented as a monotonic decreasing function of  $d_r$ , the distance between the epitope segment  $g$  and regulatory segment  $r$ .

As a result of these two selective pressures working in opposite directions, the shape of the composite pressure  $C = p_1 \times p_2$  becomes bell-shaped. The curve indicates the existence of a *window of diversity* that determines a certain advantageous range for viruses to thrive, i.e., “*Move a certain distance from here but not too far.*”

The details of our model have already been described in (Sasaki, 2013).

## Experimental Results

We conducted experiments with the model described in the previous section to investigate its dynamical behavior. Figure 2 shows the changes in diversity, which were simply measured as the number of distinct types of viruses co-circulating in the world in each time step. The dashed line shows that when the viruses evolved under only the selective pressure of immune interaction, the diversity of the viral population grew rapidly and explosively as the steps of the simulation proceeded. In contrast, the solid line shows

that when the viral evolution was under combined selective pressure from both immunity and intra-genomic constraints, the diversity did not grow explosively but saturated at a certain limit, which in this case was around 50, even in the later steps. The result indicates that our hypothetical mixture of two counter-directed selective pressures could be a possible factor to drive the evolutionary changes but at the same time limit its diversity.

Reproducing limited diversity with the simulation model is not our ultimate objective, but it is an inevitable challenge that needs to be tackled to explore the entire spectrum of temporal evolutionary behavior of the systems.

# The Origin of Money: An Agent-Based Model

Timothy A. Moran<sup>1</sup>, Markus Brede<sup>1</sup>, Antonella Ianni<sup>1</sup> and Jason Noble<sup>1</sup>

<sup>1</sup>The University of Southampton, Southampton SO17 1BJ, UK

## Abstract

The benefits of money as a medium of exchange are obvious, but the historical origin of money is less clear. An existing economic model of monetary search is reproduced as an agent-based simulation and an evolutionary algorithm is used to model social learning. This approach captures the way in which different equilibria can arise, including solutions in which one or two goods come to be used as money. In the case where monetary goods have identical properties, multiple equilibria can be reached with a dependence on the starting beliefs of agents. In our analysis we also consider the evolutionary dynamics that allow for a small chance of mutations in strategies. In some cases our findings show evolutionary paths by which use of particular monetary goods can collapse.

## Introduction

The economy is a complex adaptive system (Beinhocker, 2007). Money and its general acceptance as a medium of exchange lie at the heart of most economic activity. Its use offers a convenient alternative to barter, allowing agents who share a belief in its acceptability to trade indirectly using a monetary good that offers them no direct utility. It also offers a decentralised alternative to personal credit arrangements if the acceptance of the money is widespread.

But the value of money as a medium of exchange only arises if that money is widely accepted. The initial growth in the acceptance of money involves the reinforcement of agent beliefs from repeated successful transactions with an emergent form of money, and does not require any centralised coordination. Building an agent-based model of such a system will allow us to assess the plausibility of different historical pathways to the emergence of money, and also to study the conditions that lead to a collapse in the acceptance of a particular monetary system, a topic that economic models have so far neglected.

This paper begins by introducing an economic search model of money and its use in experiments with real and artificial agents. This model is then implemented as an agent-based simulation and extended to allow agents to learn successful trading strategies. Evolutionary paths towards the Nash equilibria are shown.

## A Search Model of Money

Kiyotaki & Wright (1989) proposed a probabilistic search and matching model that can support monetary equilibria where

useful commodities are valued as media of exchange. The economy consists of three types of agent (I, II and III) who can each hold a single unit of one of three goods (1, 2 and 3).

Fig. 1. Production and consumption in the Kiyotaki-Wright model. Type I agents consume good 1 and produce good 2, type II agents consume good 2 and produce good 3, and type III agents consume good 3 and produce good 1

Agents can produce one type of good, but only derive utility by consuming a different type of good. An agent will consume its consumption good immediately, and will produce its production good after consuming. (Thus an agent is never empty-handed.) Since no agent produces its own consumption good, inter-agent trade is necessary for agents to derive utility.

Agents have the opportunity to trade through a random matching process. In every time period, agents are randomly paired and given the opportunity to trade. The model is designed to ensure that there exists no ‘double coincidence of wants’ (Jevons, 1875) between any two agents. In other words, for trade to take place at least one agent must be willing to accept a good other than its consumption good. (This sets the stage for a good to potentially emerge as a medium of exchange.) Trade only takes place when both agents in a pair value their partner’s holding more highly than their own. Thus agents will always accept their own consumption good and they will never trade with an agent holding the same good that they are already holding.

Trade in other goods depends on the trading strategies of agents. To differentiate between the good types, the model imposes different storage costs for each. Letting  $c_j$  denote the cost of holding good type  $j$  between trading turns, then  $c_3 > c_2 > c_1$ , meaning that good 3 is the most costly to store and good 1 is the least costly.

Agents attempt to maximise their expected discounted lifetime utility. If they do not believe that any particular good will increase their chance of trading in a subsequent turn then they consider only the physical properties of the goods, and

will only accept their consumption good or a commodity that is cheaper to store than their current holding. In this **fundamental equilibrium** type I and type III agents will never trade directly, as type I agents aim to minimise costs by never accepting good 3 from type II agents. In a sense, type II agents are willing to use good 1 as money, but only because it is cheaper to store than their production good (3).

As Duffy (2001) points out: ‘An agent *speculates* when he accepts a good in trade that is more costly to store than the good he is currently storing with the expectation that this more costly-to-store good will enable him to more quickly trade for the good he desires to consume.’ For a sufficiently high utility of consumption (or, equivalently, sufficiently low storage costs) type I agents are willing to accept good 3 from type II agents, allowing them to subsequently trade directly with type III agents for their consumption good. In this case a **speculative equilibrium** is supported; type I agents are now willing to use good 3 as money, even though it costs more to store than their production good (2).

In general the trading strategies for any type of agent can be summarised in the form  $a > b > c$ , meaning that  $a$  is that agent’s favourite good and  $c$  is that agent’s least favourite good. The agent will trade any holding in exchange for good  $a$  (the agent’s consumption good), will trade holding  $b$  only in exchange for good  $a$ , and will trade holding  $c$  in exchange for any other good. The specific trading strategies of the three types of agents used in this model are shown in Fig. 2.

Equilibrium	Type I	Type II	Type III
Fundamental	$1 > 2 > 3$	$2 > 1 > 3$	$3 > 1 > 2$
Speculative	$1 > 3 > 2$	$2 > 1 > 3$	$3 > 1 > 2$

Fig. 2. Trading strategies and resulting trading patterns for the fundamental (left) and speculative (right) equilibria

### Extensions to the Search Model

The original model presented only steady-state equilibria in pure strategies. Subsequent work has considered dynamic and mixed-strategy equilibria (Kehoe, 1993), presenting a more generalised model where agents can alternate their play across their two available trading strategies.

The routes by which a monetary equilibrium could become established have been explored using both analytical and agent-based approaches (Alvarez, 2004). Replicator dynamics have been used to demonstrate analytically the dependence of an ultimate monetary equilibrium on initial conditions such as starting strategies, the storage costs of goods, and the proportions of different agent types in the economy (e.g., Luo, 1999; Sethi, 1999).

The relevance of agent-based approaches to economic modelling is well established (Vriend, 1994; Epstein & Axtell, 1996; Gintis, 1997; Duffy, 2001; Tesfatsion, 2002). Marimon et al. (1990) used classifier systems to allow agents to learn through experience those actions that resulted in positive utility, while Duffy (2001) used experiments with human subjects to appropriately calibrate an agent-based model. Başçı (1999) allowed agents to learn socially through imitation. In general both agent-based and human subject experiments found that social interaction encouraged the use of speculative strategies.

Two hypotheses are tested in the following work: an agent-based replication of the Kiyotaki-Wright model is used to test that Kiyotaki & Wright’s results still hold for small populations; and a numerical simulation of trading strategy evolution is used to test the stability of monetary equilibria in the presence of strategy mutations.

### Finite Population Model

Real economies consist of finite numbers of participants, with interesting economic behaviour exhibited even in very small economies. Agent-based simulation allows the number of interacting agents to be easily selected. The infinite-population model can be approximated with a large population of several thousand agents, or population sizes less than a hundred can be used to see if the same results hold in small communities. Another advantage of running simulations with small populations is that results can be compared to laboratory data from behavioural experiments. Such experiments have typically used less than 30 agents playing a repeated game for less than 100 periods.

### Initialisation

A population size is chosen and an initial population of agents is created, with an equal number of agents of each of the three types. For simplicity the population sizes were chosen to be a multiple of six to ensure an equal distribution across consumption types and to allow all agents to form trading pairs. In the basic model the consumption type also uniquely defines the agent’s trading strategy, with all agents playing fundamental strategies. Agents are initially holding their production goods, representing an economy with no initial endowments or natural resources.

### Trade

Each turn agents are randomly paired into potential trading partnerships and attempt to trade according to their pre-defined trading strategies. This random pairing treats all agents as equally likely to meet, with no memory of past interactions or any attempt to anticipate the outcome of a particular pair. If a successful trade results in an agent holding its consumption good then that agent immediately consumes its holding and gains positive utility by doing so. That agent then immediately produces a new unit of its production good, which becomes its new holding.

At the end of every turn each agent pays the storage cost for its current holding. The utility of an agent consuming its own specific consumption good ( $u$ ) and the storage costs for each good ( $c_1$ ,  $c_2$  and  $c_3$ ) are defined globally and are the

same for each type of agent. Agents record their lifetime utility. When the model is expanded to allow agent trading strategies to evolve, this lifetime utility record will be used as a measure of the fitness of each agent.

### Results of the Agent-Based Model

A single run of the simulation consists of the creation of a population of new agents, the interaction of those agents over a number of turns, and data collection to allow the behaviour of those agents to be summarised.

Data was collected for ease of comparison with results in Kiyotaki & Wright (1989). This consisted of the stocks ( $x$ ) of each good at the end of the turn; the number of transactions ( $t$ ) involving that good during the turn; the 'velocity' ( $v$ ) of each good; and the 'acceptability' ( $a$ ) of each good. These last two values were chosen as two measures of the 'moneyness' of each good, with velocity ( $v = t/x$ ) a more traditional measure (Fisher, 1909) showing the number of transactions weighted by the supply of the good in the economy, while acceptability ( $a = t/o$ ) is the probability that a good will be accepted in trade (Kiyotaki & Wright, 1992), weighting transactions by the number of times a good is offered ( $o$ ).

Results of a single run are shown for a small population of 90 agents (Fig. 3). Solid lines show the levels at the end of each trading turn. Because fundamental equilibrium trading strategies were imposed the system very quickly settles on the equilibrium levels for stocks, transaction, velocities and acceptabilities, taking less than 10 trading turns to do so.

To record these equilibrium levels, averages are calculated for each good from period 10 onwards, and shown as dotted lines. Even for small populations the results are consistent with large- and infinite-population models.

Fig. 3. Results showing stocks, transactions, velocities, and acceptabilities of three goods over time for a single run of the agent-based model with 90 agents

### Evolving Trading Strategies in the Agent-Based Model

The consistency with the infinite population results indicates that an agent-based model is appropriate for studying the emergence of monetary equilibria. The agent-based model can be modified to allow agents to adapt their behaviour. Instead

of imposing unchanging equilibrium trading strategies on the agents, agents are now allowed to adjust their trading strategies based on their relative success. A basic evolutionary algorithm was used to allow successful preferences to be retained, unsuccessful preferences to be replaced, and new or forgotten preferences to emerge.

Instead of imposing equilibrium trading strategies, agents were given trading strategies that were initially completely random. Regardless of consumption type, agents had a 1/6 probability of being assigned one of the initial trading strategies:

$$\begin{array}{lll} 1 > 2 > 3 & 1 > 3 > 2 & 2 > 1 > 3 \\ 2 > 3 > 1 & 3 > 1 > 2 & 3 > 2 > 1 \end{array}$$

These initial trading strategies are unlikely to be beneficial to the agent, as in many instances they will lead to an agent rejecting its consumption good. However, the evolutionary model will allow agents to adapt their trading strategies to match those that have been successful in the previous generation, allowing us to test whether this model is sufficient for a monetary equilibrium to emerge.

### Trading Strategy Fitness

The simulation is broken down into a number of generations ( $G$ ), each consisting of a number of trading periods ( $T$ ). At the start of the first generation agents are given random trading strategies as described above. Play within a single generation is the same as described above, with agents being randomly paired and trading when both agents in a pair prefer their partner's holding to their own, given their current trading strategy. Agents keep track of their lifetime utility, which increases whenever they receive and consume their consumption good, and decreases by the storage cost of their holding at the end of each trading turn.

At the end of each generation agents are ranked by their total utility across all the trading turns in that generation. Agents who consume a relatively large amount, or spend fewer turns carrying the goods with the highest storage costs, will have the highest utilities within that generation. This total utility level is used as a measure of the fitness of that agent's trading strategy, with higher fitness trading strategies more likely to survive into subsequent generations.

### Imitation and Mutation of Trading Strategies

The agent population is first divided by consumption type. Within each consumption type, the 80% least successful agents are discarded. Each of the most successful 20% of agents then produces four offspring, so that the population size remains unchanged between generations.

Offspring are initially a perfect copy of their parent, with the same consumption type and the same trading strategy. There is then a 10% chance that each child will slightly mutate its trading strategy by swapping the order of two goods in its priority list. The two goods that are swapped in this way are chosen randomly with equal probability of any two goods being selected, i.e. the first and second item may be swapped with  $p = 1/20$ , or the second and third item may be swapped with  $p = 1/20$ .

This mutation mechanism means that at most two items are swapped in the trading strategy, with zero chance of a larger mutation or multiple mutations within a generation.

## Results of the Evolutionary Model

In all cases a population size of 300 agents (100 of each consumption type) is chosen. Generations consist of  $T = 1000$  trading turns, and trading strategies are reproduced and mutated across  $G = 50$  generations.

Results of the evolutionary model are plotted as charts that show the dominant trading strategies of each type of agent against generational time. Coloured squares are used to show the proportion of each type of agent using a given trading strategy in a given generation. Colours represent agent consumption type (type I in red, type II in green and type III in blue), with the intensity of that colour showing the proportion of the population who are choosing that trading strategy. Saturated colours represent a trading strategy chosen by all or most agents of a particular type, while very weak colours signify a trading strategy chosen by few or no agents of that type.

Fig. 4. Agent-based evolution of speculative strategy ( $u = 100$ ,  $c_1 = 1$ ,  $c_2 = 4$ ,  $c_3 = 9$ , average over 20 runs)

When utility of consumption is suitably high, type I agents benefit by adopting the speculative trading strategy, as shown in Fig. 4. Although it takes several generations for agents to adapt, they ultimately settle on the speculative equilibrium.

With lower utilities for consumption ( $u < 20$ ), holding costs become increasingly significant and small populations of agents may not discover the fundamental equilibrium.

Fig. 5. Failure to discover fundamental strategy ( $u = 10$ ,  $c_1 = 1$ ,  $c_2 = 4$ ,  $c_3 = 9$ , average over 20 runs)

Fig. 5 shows that type II agents prefer a trading strategy that permanently minimises their storage costs by accepting the lowest cost good (1) and never releasing it. Surprisingly, they do not learn to accept their own consumption good. This shows that agents in small-population runs of our model can adopt and persist with trading strategies that were not predicted by analytic approaches. The finding is intriguing but we expect that it would not occur given a larger population and indeed our focus here is not on the discovery of consumption goods (surely a no-brainer in evolutionary terms) but on the origins of monetary exchange.

## Evolving Trading Strategies in a Large Population Model

An alternative to simulating the evolution of individual agent behaviours is to simulate the evolution of the population as a whole. In their original paper, Kiyotaki & Wright computed elements  $p_{ij}$  of a population array  $\mathbf{p}$ , with the elements corresponding to the proportion of type  $i$  agents holding good  $j$  in the steady state reached after a number of trading steps. In Kiyotaki & Wright these 6 elements of  $\mathbf{p}$  were sufficient to completely describe the population because each consumption type held a fixed (fundamental or speculative) trading strategy.

To study the evolution of trading strategies using a population array, new elements need to be added to allow agents of the same consumption type to use different trading strategies. Following a methodology similar to Luo (1999) and Sethi (1999) who studied this problem analytically, the population array  $\mathbf{p}$  is reconstructed using 12 elements, with each element of the array representing a triplet of consumption type, holding and trading strategy.

Each consumption type is now permitted two trading strategies, both of which still prioritise that type's consumption good. The interesting question in monetary search is not whether an agent discovers his consumption good (which he must in order to gain any utility), but how that agent treats non-consumption goods in a monetary capacity. In this three-good system the agent can prioritise the remaining two non-consumption goods in two ways: either it can prefer to hold its cheaper non-consumption good (a fundamental trading strategy) or it can prefer to hold its more expensive non-consumption good (a speculative trading strategy).

This is a slightly different labelling than employed in Sethi (1999), which treats consumption types as preferring to hold their production good or their non-production good. In the case of type I and type III agents, their production good is also the cheaper of their two non-consumption goods. But in the case of type II agents, their production good is the more expensive of their non-consumption goods.

## Initialising the population

The population array is composed of twelve elements corresponding to one of three consumption types, each of whom may hold one of their two non-consumption goods and one of two trading strategies (fundamental or speculative). Each consumption type comprises one third of the population,

and the population is initialised so that all agents are holding their production good. The proportion of each trading type following each of their two possible trading rules can be varied. As an example, if all consumption types started with equal proportions playing each possible trading strategy, the initial elements of the population array would be:

$$\begin{array}{lll} p_{I(2)123} = 1/6 & p_{II(1)213} = 0 & p_{III(1)312} = 1/6 \\ p_{I(3)123} = 0 & p_{II(3)213} = 1/6 & p_{III(2)312} = 0 \\ p_{I(2)132} = 1/6 & p_{II(1)231} = 0 & p_{III(1)321} = 1/6 \\ p_{I(3)132} = 0 & p_{II(3)231} = 1/6 & p_{III(2)321} = 0 \end{array}$$

where the subscripts represent consumption type-(holding)-trading strategy.

### Trading to a steady state in holdings

After initialisation the simulation iterates through an outer loop. At the beginning of the iteration all agents' holdings are reallocated to the production goods of that type. Agents already have trading strategies, either from a previous iteration or from initialisation.

The population shares are updated to reflect repeated matching by agents for the given trading strategies. Any particular match between type  $i$  and  $j$  will occur with probability  $p_i p_j$ , with trade occurring if it is beneficial to both members of the pair as in all earlier models.

If as the result of a match an agent ends up holding its consumption good, it immediately consumes it and replaces it with its production good. The population share resulting from such a match is therefore added to the element corresponding to that agent's consumption type, trading strategy and production good. After multiple trading steps a steady-state in goods is reached.

### Replication of successful trading strategies

When the holdings reach a steady state – i.e. the holdings on two subsequent turns are sufficiently similar (within a specified tolerance level, set as  $10^{-6}$  for the results in this paper) – the trading phase of the simulation terminates, and the time-discounted expected lifetime utilities of different types of agent are calculated.

Agents are given a great degree of foresight while calculating these expected lifetime utilities. For the reported results, agents were allowed to look-ahead 100 periods using a discount factor of  $\beta = 0.9$ . Any calculation with more than about 50 periods is a good approximation to an infinitely-lived, perfectly rational agent.

Agents of a given consumption type and holding are then allowed to imitate each other's strategies based on their relative expected utilities. A discretised version of the replicator equation (Weibull, 1995) is used to adjust the population shares across trading strategies for each consumption type-holding pair. The population share for a given consumption type ( $t$ ), holding ( $h$ ) and trading strategy ( $s$ ) is updated as:

$$p_{t(h)s} = p_{t(h)s} \left( 1 + r \left( U_{t(h)s} - \frac{p_{t(h)s} U_{t(h)s} + p_{t(h)s'} U_{t(h)s'}}{p_{t(h)s} + p_{t(h)s'}} \right) \right)$$

where  $s'$  is the alternative trading strategy for the same consumption type-holding pair,  $U_{t(h)s}$  are the expected discounted lifetime utilities already calculated, and  $r$  is a scaling factor used to represent selection pressure. The proportion of the population using a particular trading strategy increases if that strategy yields a higher expected utility than the population-weighted average of the two alternative strategies, at a speed proportional to the difference. The proportion playing the less successful strategy will shrink.

After performing a single trading strategy update step, the population is reinitialised to hold their production goods and the next iteration begins with a new round of trading to a steady state in holdings. This process continues until successive updates of the entire outer loop produce no further change in trading strategy share.

After each trading step and trading strategy update the population is re-normalised to ensure that small numerical errors do not result in the creation or destruction of holdings (during the trading steps) or a re-allocation across consumption types (during strategy updates).

The same general results are obtained for less far-sighted agents. The number of future time periods considered in expected utility calculations was chosen to allow relatively rapid convergence to a trading strategy equilibrium, but limiting this amount of foresight only slows the learning process, it does not change the end result. As long as agents consider at least one period into the future, they are able to appreciate the benefits of a monetary good as a medium of exchange.

## Results of the Large Population Model

A variety of setups were used to explore conditions under which the different equilibria of the Kiyotaki-Wright model could be reached.

Results are visualised in the trading strategy space of the three agent types. Each consumption type can play one of two strategies: either the fundamental trading strategy that favours holding the lower numbered good (the cheaper good in the conventional setup of  $c_1 < c_2 < c_3$ ), or the alternative speculative trading strategy that favours the higher numbered (more costly) good.

After each trading strategy update, the proportion of each consumption type playing that type's fundamental strategy was recorded, and these proportions used to label the axes of a cube that describes the strategies of all agents in the economy. The 0 of the axis corresponds to all agents playing their speculative trading strategy, while 1 corresponds to all agents playing their fundamental trading strategy.

A selection of starting points was chosen (27 points formed by all possible combinations of [0.25, 0.5 and 0.75] across the three consumption types) and trading strategies allowed to evolve under the rules described above. When plotted these evolving trading strategies tend to trace paths from a uniform three dimensional grid in the centre of the trading strategy space towards one of the equilibria at the corners of the cube. This equilibrium was dependent only on utilities and costs, and not on the particular starting trading strategies.

Results show a representative evolution of trading strategies for the starting mix of trading strategies (1/2, 1/2, 1/2).

Storage costs and utilities have been chosen for consistency with Duffy (2001), with  $c_1 = 1$ ,  $c_2 = 4$  and  $c_3 = 9$ .

### Fundamental Equilibrium

With  $u = 10$  (Fig. 6), all paths rapidly converge on the fundamental equilibrium (1,1,1), with all agents preferring lower storage cost goods to higher storage cost goods (type I:  $1 > 2 > 3$ , type II:  $2 > 1 > 3$ , type III:  $3 > 1 > 2$ ).

Fig. 6. Fundamental equilibrium (rapid convergence)

Increasing the utility of consumption increases the incentive for type I agents to speculate and experiment with holding a monetary good, as the benefits of more frequent trade are greater relative to the fixed costs of holding goods. With  $u = 20$  and costs unchanged (Fig. 7) trading strategies still converge on the fundamental equilibrium, but far more slowly.

Although type II agents still converge rapidly on their fundamental trading strategy, there is very little evolutionary pressure for a mixed population of both fundamental and speculative type I agents to move towards the fundamental trading strategy, as the expected utilities of either trading strategy are very similar.

Fig. 7. Fundamental equilibrium (slow convergence)

### Speculative Equilibrium

When the utility of consumption is sufficiently high, type I agents can increase their expected utility by accepting good 3 from type II agents. The additional expense of holding this high storage cost good is offset by the increased expectation of direct trade with type III agents for good 1, the type I agents' consumption good.

Kiyotaki & Wright calculate the critical level at which type I agents should speculate as dependent on the level of utility, the holding costs and the proportions of type II and type III agents who are holding good 1. Type I agents should speculate if  $c_{13} - c_{12} < (p_{31} - p_{21})\beta u_1$  (Kiyotaki & Wright, 1989).

This can be seen when the utility of consumption is set sufficiently high, with  $u = 100$  in Fig. 8. Convergence to this speculative equilibrium occurs rapidly, with all three consumption types converging on their equilibrium strategy in similar timescales.

Fig. 8. Speculative equilibrium

To produce Fig. 8 an appropriate speed of trading strategy replication ( $r$ ) needed to be chosen. Lower values of  $r$  mean that the system takes longer to reach an equilibrium, but the more gradual replication of trading strategies stops strategies from becoming caught at alternative equilibria.

This occurs because a trading strategy can only be replicated if it still exists within the population. Once entirely eliminated, the replicator equation used above will not allow a trading strategy to re-emerge, as it has a zero weighting in the population average. If  $r$  is too high those paths that pass close to the corners (1,1,0) and (1,1,1) may become trapped at these alternative equilibria before reaching the speculative equilibrium (0,1,1).

As well as slowing down the speed of convergence, another way to ensure that the system does not approach a sub-optimal equilibrium due to these numerical errors is to introduce a small mutation rate that allows extinct trading strategies to reappear. In the cases discussed above such a mutation rate will only temporarily move the system away from the equilibrium, but becomes interesting in the case of a mixed equilibria system.

## Multiple Equilibria

This framework which had been used to reproduce the evolutionary dynamics described analytically in Sethi (1999) can also be used to consider the case of identical goods, proposed in an example in Luo (1999). If goods are either identical or very similar, the particular type of money used in the economy may have a sensitive dependence on the initial mix of agent trading strategies.

By relaxing the cost ordering of Kiyotaki-Wright and setting the storage cost of goods equal ( $c_1 = c_2 = c_3 = 0$ ), the particular monetary equilibrium depends only on the initial trading strategies used by agents, as shown in Fig. 9 where  $(1/3, 2/3, 1/3)$  is a critical point around which trading strategies significantly diverge. Trading strategies started at the 125 points formed by allowing each starting trading strategy to diverge from this critical point by  $[-0.02, -0.01, 0, 0.01, 0.02]$ .

Fig. 9. Multiple equilibria for identical goods ( $u = 100, c_1 = c_2 = c_3 = 0$ )

Trading strategies can end at one of the three 'speculative' equilibria, shown in red  $(0,0,0)$ , green  $(0,1,1)$  and blue  $(1,1,0)$ , or at an equilibrium (shown in grey) where one consumption type continues to be composed of agents playing both 'fundamental' and 'speculative' strategies.

The labels 'fundamental' and 'speculative' are no longer meaningful as all goods have an identical holding cost. However, the particular good that is used as a medium of exchange depends on the equilibrium point that is reached, which depends only on the starting mix of trading strategies:

- $(0,1,1)$ : Type I accept good 3, type II accept good 1
- $(0,0,0)$ : Type III accept good 2, type I accept good 3
- $(1,1,0)$ : Type II accept good 1, type III accept good 2

## Strategy Mutation

With trading strategy imitation described by the replicator equation, once agents reach an equilibrium (at a corner or edge of the trading strategy space) they will remain there, as there is no process for forgotten strategies to be rediscovered.

Allowing a small degree of trading strategy mutation after the replication phase allows forgotten trading strategies to return. Each consumption type-holding pair is mutated

independently. In each case a random number is drawn uniformly from the interval  $[-0.001, +0.001]$  and multiplied by the proportion of the population playing either trading strategy in this pair. The proportion of agents playing the fundamental trading strategy is then increased by this amount, and the proportion playing the speculative trading strategy decreased by the same amount, with a normalisation step to ensure that this does not result in either proportion becoming less than zero.

In the case of the fundamental and speculative equilibria discussed above these mutations have little effect. Mutations cause the trading strategies to fluctuate around the equilibrium, but strategy replication takes the system back towards it.

However, in the case of the mixed equilibria, strategy mutations can drive the system around the edges of the trading strategy space, permitting sudden transitions from one monetary equilibrium to another. Starting from the equilibrium at  $(0,1,1)$ , the results of strategy mutations are shown in Fig. 10.

Fig. 10. Trading strategy mutation shifts monetary equilibria

Fig. 11. Cycling through trading strategy equilibria

Fig. 11 shows the speed of these transitions. Trading strategies initially move slowly along the edge of the trading strategy space. Along these edges one consumption type is split into players playing both fundamental and speculative trading strategies, while the other two consumption types are playing a single strategy. The mutation step allows these single-strategy players to experiment with their alternative strategy, which provides an additional incentive for the two-strategy player to shift in favour of the second strategy. Ultimately a critical point is reached where enough of the current two-strategy players are playing the second strategy to cause the rapid transition to a new equilibrium. At this point the two-strategy player has an incentive to play only their second strategy, and a new consumption type begins experimenting with their alternative strategy.

This shows how the gradual shift in the acceptance of one type of money by one type of agent can tip the population structure to the point where an entirely new good becomes accepted as money.

For instance, in the initial move from (0,1,1) towards (0,0,1), with a sudden transition to (0,0,0): Initially good 3 is used as money by type I and good 1 is used as money by type II. Type II agents then increasingly refuse to accept good 1, driving the system towards an equilibrium where their own production good is the unique monetary good. However, at a critical point the system shifts as type III agents begin accepting good 2 as a monetary good.

This process repeats. In each case an agent shifts its trading strategies in favour of creating a monopoly in money production, ultimately resulting in a shift that begins a cycle where the original agents production good is rejected as money entirely.

## Discussion

It is encouraging that the models of Kiyotaki & Wright (1989) and Sethi (1999) can be reproduced in both agent-based and numerical simulations that support the original analytic results. The findings presented here explicitly confirm the infinite-population based estimates of Sethi in the limit of very small population size and in the presence of noise in the evolutionary dynamics.

Speculative, fundamental, and mixed equilibria can each be supported if appropriate consumption utilities and storage costs are chosen. If goods are homogenised by setting their storage costs to be equal, multiple equilibria can also be supported; this finding provides a way in to modelling problematic phenomena such as competing currencies (Hayek, 1976) or monetary collapse.

There are many ways in which this framework could be extended. One of the most obvious would be to consider more realistic economies in which more than three types of agents trade more than three types of goods; in which goods differ in their properties such as durability; and in which prices can vary. Another line of extension would be to investigate the effect an evolution that is constrained to real-world social networks has on monetary search. The current model assumes a complete trading network, where any two agents may meet and attempt to trade with equal probability. Real trading environments tend to have strong cultural, social or geographical roots, suggesting that investigating the

evolution subject to more constrained interaction patterns could be an important step in motivating the maintenance of multiple competing currencies.

# BEYOND THE SCHELLING'S SEGREGATION MODEL: IS IT EQUIVALENT TO BE REPULSED BY DISSIMILAR RATHER TO BE ATTRACTED BY SIMILAR?

Philippe Collard

## Abstract

From the Schelling model of segregation, we derive models of group formation that shed light on segregation or mixing patterns observed in spatial grid networks. Individuals have types and see type-dependent benefits or drawback from their neighbours: this leads each one to be attracted or repulsed by its own like or unlike. This framework allows to studying many spatial phenomena that involve individuals making location choices as a function of the characteristics and choices of their neighbours. Our goal is to grow social structures *in silico* and to ask if related micro-specifications generate similar macro-phenomena of interest. Regarding (i) the amount of segregation-mixing, (ii) the congruence between micro-motives and macro-behaviour and (iii) the nature of frontier between clusters, we examine the properties of the steady-state equilibrium.

## Introduction

This article is based on the Schelling's checkerboard model of residential segregation ?; this model has become one of the most cited and studied models in many domains as economics, sociology, complex systems science... ? ? ?. In the Schelling model the world is a 2-dimensional *grid* composed either by locations occupied by agents or by vacant ones. The perception of an agent is centred on its local neighbourhood only. There are two types of agents. The behaviour of one agent consists to move away on if it is not satisfied. Satisfaction is relative to the *proportion* of agents with a dissimilar type in the neighbourhood.

In this paper, the goal is to grow social structures *in silico* and to ask if related micro-specifications generate similar macro-phenomena of interest. We define a generic framework in order to shape several models with various micro-motives. This family of models allows us to show that a wide variety of macro-behaviours can emerge despite the fact that they come from a same mould and share some common features. In particular, we propose to consider the following issues: Q1) Is it equivalent to flee regarding the proportion of dissimilar agents among the neighbourhood agents rather than the number of dissimilar agents in the full set of neighbours? Q2) Is it equivalent to be repulsed (resp. attracted) by

dissimilar neighbours rather to be attracted (resp. repulsed) by similar neighbours ?

## The AR models

To answer these questions, we define the family of attraction-repulsion models (AR models). For all these models, the world is a 2-dimensional *grid* where nodes-cells represent either locations occupied by agents or vacant ones. A vacant cell could be occupied by an agent later. The perception of an agent is centred on its local neighbourhood only. One assumes that the neighbourhood of an agent is constituted both by the nearest agents and the vacant cells surrounding him: in this paper we consider the *Moore* neighbourhood composed of the eight nearest cells surrounding it. Let be  $V$  the set of vacancy cells and  $A$  the set of agents. We assume that the number of agents ( $\#A$ ) is conserved and the total volume in which they move ( $\#A + \#V$ ) is constant. The density of agents is the ratio  $d = \frac{\#A}{\#A + \#V}$ . There are two types of agents and each agent has its own type. The agent's type can never change. For convenience we will denote by a color, *blue* and *yellow*, the two possible types. Yellow and blue agents can be interpreted as individuals representing any two groups in society (two genders, smokers and non-smokers, etc.) Let  $B$  (resp.  $Y$ ) the set of agents in the *blue* type (resp. *yellow* type). So,  $\#B + \#Y = \#A$  and, at the global level, the basic hypothesis is ( $\#B = \#Y$ ). Each agent is satisfied or unsatisfied according to its own type and the type of its neighbours.

## Micro motives

In the Schelling model one agent moves if its utility  $u$  falls below a certain threshold ( $u \leq \tau$ ). In this section we generalize this model in considering different utility functions and we propose to study the two cases where the utility is either below or above the threshold  $\tau$ .

**Utility functions** For each agent  $a_i$ , considering only the agents in its neighbourhood, we define the two utility functions:

$$\Delta_i = \begin{cases} \frac{\delta_i}{\sigma_i + \delta_i} & \text{if } \sigma_i + \delta_i \neq 0 \\ 1 & \text{else} \end{cases} \quad (1)$$

$$\Sigma_i = \begin{cases} \frac{\sigma_i}{\sigma_i + \delta_i} & \text{if } \sigma_i + \delta_i \neq 0 \\ 1 & \text{else} \end{cases} \quad (2)$$

where  $\delta_i$  (resp.  $\sigma_i$ ) is the number of dissimilar (resp. similar) nearby for the agent  $a_i$ .

In the same way, considering the set of all the cells in the neighbourhood of the agent, we define the two utility functions:

$$\Delta'_i = \frac{\delta_i}{neighbourhoodSize} \quad (3)$$

$$\Sigma'_i = \frac{\sigma_i}{neighbourhoodSize} \quad (4)$$

Let's note that  $\Delta_i + \Sigma_i = 1$ , while, in general,  $\Delta'_i + \Sigma'_i \neq 1$ .

So, given a threshold  $\tau$  in the range  $[0, 1]$ , there are potentially eight ways to express a condition to be satisfied (Table ??). Let's note that the model  $M_0$  corresponds to the Schelling model of segregation.

Table 1: Potential conditions to be satisfied

Model	$u \leq \tau$	Model	$\tau \leq u$
$M_0$	$\Delta \leq \tau$	$M_4$	$\tau \leq \Delta$
$M_1$	$\Delta' \leq \tau$	$M_5$	$\tau \leq \Delta'$
$M_2$	$\Sigma \leq \tau$	$M_6$	$\tau \leq \Sigma$
$M_3$	$\Sigma' \leq \tau$	$M_7$	$\tau \leq \Sigma'$

**Complement model** Two models  $M_i$  and  $M_j$  are said to be *complementary* iff the conditions to be satisfied are logical complementary; then, we note  $M_j = \overline{M_i}$ .

Obviously the equation  $\overline{\overline{M}} = M$  holds. We have  $M_4 = \overline{M_0}$ ,  $M_5 = \overline{M_1}$ ,  $M_6 = \overline{M_2}$  and  $M_7 = \overline{M_3}$ .

**Dual model** Two models  $M_i$  and  $M_j$  are said *dual* iff the conditions to be satisfied are dual; we note  $M_j = M_i^*$ . We say that two conditions  $(U_i \leq \tau_i)$  and  $(\tau_j \leq U_j)$  are *dual* iff  $(U_i, U_j) \in \{(\Delta, \Sigma), (\Sigma, \Delta), (\Delta', \Sigma'), (\Sigma', \Delta')\}$ .

Obviously the equations  $\forall i, M_i^{**} = M_i$  and  $\overline{(M_i^*)} = (\overline{M_i})^*$  hold. More, as  $\Delta + \Sigma = 1$ ,  $M_0^* = M_0$  and  $M_2^* = M_2$ . Finally, we have  $M_4 = M_2^* = M_2$ ,  $M_5 = M_3^*$ ,  $M_6 = M_0^* = M_0$  and  $M_7 = M_1^*$ .

**AR models** All this leads us to consider six models of segregation/mixing only. For each model, table ?? gives the local condition under which an agent is satisfied. Let's note that all the AR models are defined from the two models  $M_0$  and  $M_1$  only.

Table 2: AR models: condition to be satisfied

$M_0 \equiv (\Delta \leq \tau)$	$M_1 \equiv (\Delta' \leq \tau)$	$M_1^* \equiv (\tau \leq \Sigma')$
$\overline{M_0} \equiv (\tau \leq \Delta)$	$\overline{M_1} \equiv (\tau \leq \Delta')$	$\overline{M_1^*} \equiv (\Sigma' \leq \tau)$

## Rules governing agents movement

In the standard Schelling's models, as soon as an agent is unsatisfied, it moves to another place where it becomes satisfied. So, the local behaviour is an optimisation process which needs any agent to access information about any cell-location in order to compute its utility function in the target cell.

To stay is in the spirit of the complex systems paradigm, in AR models there is no decision-rule to decide whether or not an agent gains an advantage by means of migration towards a target cell. To find a new place, an unsatisfied agent uses a simple rule (what we call the *Eulogy to Fleeing (EF)* rule): *a location is randomly chosen from the world and the agent moves into it if and only if this location is vacant*. Consequently, an agent may move at random towards new locations by allowing utility-increasing or utility-decreasing moves. As the moves do not equate to immediate benefits, it is challenging to predict the overall emerging effect.

## Macro behaviour

For the six AR models, simulations will show that, applying the *EF rule*, in many cases, the population reaches a state where all the agents are satisfied or, at least, a large proportion of agents are satisfied. In the first case we will say that there is *convergence* and in the second case *quasi-convergence*. In this paper, we do not discuss the conditions which guarantee convergence towards equilibrium or quasi-equilibrium; we select system conditions in which one of these two cases occurs. Let's note that the *EF* rule has already been used within Schelling's models, leading the system towards equilibrium ?.

**Segregation vs. mixing** According to its micro-motive, we may assume that each AR model leads at the global level of the population either towards *segregation* or *mixing*. For a given model, regarding if the micro-motive is based on *repulsion* or *attraction* in the face to *similar* or *dissimilar* neighbours, we indicate if the macro-behaviour should be rather either segregation or mixing (Table ??). Given to models  $M_i$  and  $M_j$ :

- if  $M_j$  and  $M_i$  are *complementary*, then the respective macro-behaviour and micro-motives are opposed but the target neighbours are identical.
- if  $M_j$  and  $M_i$  are *dual*, then the respective macro-behaviour are identical but the micro-motives and target neighbours are opposed.

Table 3: AR models: attraction vs. repulsion

Model	Micro motive	Target neighbours	Macro behaviour
$M_0$	repulsion	dissimilar	segregation
	attraction	similar	segregation
$M_1$	repulsion	dissimilar	segregation
$M_1^*$	attraction	similar	segregation
$\overline{M}_0$	attraction	dissimilar	mixing
	repulsion	similar	mixing
$\overline{M}_1$	attraction	dissimilar	mixing
$\overline{M}_1^*$	repulsion	similar	mixing

Because the  $M_0$  (resp.  $\overline{M}_0$ ) model is *self-dual*, it can be view either as a model of repulsion against its dissimilar (resp. similar) agent-neighbours or a model of attraction for its similar (resp. dissimilar) agent-neighbours; in both case there is emergence of segregation (resp. mixing).

**An index to measure the segregate-mixing ratio** In order to gain some insight into the segregation-mixing level, it is necessary to measure the global state of segregation of the world. We reformulate measures proposed by ?, ? and ?.

First, for each time  $t$ , we define a global measure of *similarity* as:

$$s(t) = \frac{1}{\#A} \sum_i^{\#A} (1 - \Delta_i(t))$$

Then we define the *segregate-mixing* index by:

$$segMix = \begin{cases} \frac{s - s_{rand}}{1 - s_{rand}} & \text{if } s \geq s_{rand} \\ \frac{s - s_{rand}}{s_{rand}} & \text{else} \end{cases} \quad (5)$$

where  $s_{rand}$  is the expected value of the measure  $s$  implied by a random allocation of the agents in the world. So, a zero *segMix* index corresponds to a random positioning of the agents. The maximum value of 1 corresponds to a configuration with two homogeneous patterns (complete segregation into two same-colour groups), whereas negative values point towards highly mixed populations.

**An index to measure the congruence between micro-motives and macro behaviour** We define the *micro-Macro* index as :

$$mM = \begin{cases} \frac{\overline{u}_i}{\tau} & \text{if } \tau \geq \overline{u}_i \\ \frac{1 - \overline{u}_i}{1 - \tau} & \text{else} \end{cases} \quad (6)$$

where  $u$  is the utility function and  $\overline{u}_i = \text{mean}_i(u_i)$ . The value 1 corresponds to the theoretical optimal case where dynamics build exactly the needed liveable configurations: in this case the congruence between micro and macro levels is maximum. The value 0 corresponds to the extreme

case where dynamics build much more liveable configurations than necessary to reach the emergent macro-state: in this case there is no congruence between micro and macro levels.

**Frontier** A frontier is a generic concept that has different instantiations depending on the context in which it is considered. A common class of frontiers is found in the geographical domain, where they appear as fronts. The interest we take in this concept lies on two aspects: from a *static* standpoint, a frontier enables the separation of incompatibilities; however, as it allows at the same time some form of communication between them, a *dynamic* perspective is also relevant. So, we consider a frontier as a structure which both determines the “borderland” between two aggregates of opposite types and allows communication between them ?.

**Definition** A *frontier* is composed of the cell-locations where contact occurs between two dissimilar agents. We consider contacts as being of two types: *direct* or *indirect*. A direct-contact refers to agents being directly linked, whereas an indirect-contact is mediated through a vacant location. In the real world, a direct-contact can be exemplified through the contact of a healthy person with a person having a communicable disease, whereas an indirect-contact is achieved through some intervening medium *e.g.* air. Let  $D$  (resp.  $I$ ) the set of direct (resp. indirect) contacts:

$$D = \{(a_i, a_j) \in B \times Y \mid a_j \in N(a_i)\}$$

$$I = \{(a_i, a_j, v) \in (B \times Y \times V) \mid v \in N(a_i) \cap N(a_j)\}$$

where  $N(a_k)$  is the neighbourhood of the agent  $a_k$ . Then we define the frontier as:  $F = (A_F \cup V_F, E_F)$ ; where  $A_F$  is the subset of agent-cells that are at least one coordinate of an element of  $D$  or  $I$ ,  $V_F$  is the subset of vacant cells that are at least one coordinate of an element of  $I$  and  $E_F$  is the set of links between neighbouring cells of  $F$ .

**Characteristics of a Frontier** To enable consistent comparisons of frontiers, we take into account their importance relative to the entire world and their openness. Thus, we define what we mean by a frontier’s *occupancy* and *porosity*. These two criteria are chosen to address the ambivalence between separation and exchange, as the main characteristic of a frontier.

We define the *occupancy* as the ratio between the number of cells forming the frontier and the total number of cells in the world:  $occupancy(F) = \frac{\#(A_F \cup V_F)}{\#A + \#V}$

For instance, if each agent is placed on a checkerboard according to its type<sup>1</sup>, all the agents are on the frontier and so the occupancy is equal to 1.

In Material Physics, *porosity* is a measure of how much of a rock is open space in between spores or within cavities of

<sup>1</sup>On a checker-board, a yellow agent is on a black square while a blue agent is on a white square, so there are no vacant places.

the rock  $\tau$ : it is defined as the ratio of the occupancy of voids in a material to the occupancy of the whole. By analogy, we consider the elements of  $D$  as representing the voids in a material (a lack of communication impediments). We define then the *porosity* as the proportion of direct-contacts: 
$$porosity(F) = \frac{\#D}{\#D + \#I}$$

### Simulation Framework

Experiments are performed *via* the *NetLogo* multi-agent programmable modelling environment  $\tau$ . The pseudocode for simulating AR models is defined in algorithm  $\tau\tau$ ; by instantiating the utility function *via* the update satisfaction method we obtain the six simulators that we experiment with.

Simulations are performed on a  $L \times L$  lattice of locations:  $L$  is set to 50 and the density of agents  $d$  is 90% which are standard values to simulate the Schelling model  $\tau$ . The agent set is positioned in a random initial configuration, such that the vacant locations and the two types of agents are well mixed and the *segMix* index is close to 0.

### Models of segregation

In this section we consider among the six AR models the ones which lead to segregation. In order to compare the resulting shapes we will use (i) the *segMix* index, (ii) the  $mM$  congruence index and (iii) the characteristics of the frontier which emerges between clusters of agents with a same type.

#### $M_0$ model

In the Schelling's segregation model, agents are satisfied if the proportion of dissimilar neighbours among the agent-neighbours is below a threshold and unsatisfied if the proportion of similar neighbours is above this threshold. The

Schelling's model  $\tau$  is a particular case among the AR models: it corresponds to  $M_0$ . To compute satisfaction, we consider the condition ( $\Delta \leq \tau$ ) where  $\tau$  can be interpreted as the *tolerance* of the agents against their dissimilar neighbours. If  $\tau \ll 0.5$ , agents are rather intolerant, else if  $\tau \gg 0.5$  agents are rather tolerant.

Because the smallest step in the fraction of satisfied neighbours is  $1/8$ , we consider the two examples with  $\tau = 3/8$  and  $\tau = 5/8$ : if  $\tau = 0.375$ , agents are rather intolerant: one agent  $a_i$  will be satisfied in eighteen cases. If moreover the agent has exactly eight nearby agents, it cannot suffer more than three dissimilar neighbours. At the opposite, for the value  $\tau = 0.625$  all the individuals are rather tolerant and, if moreover an agent has exactly eight nearby agents, it can suffer at most five dissimilar agents in its vicinity.

**segregation** Because  $M_0$  is self-dual, the dynamics can be interpreted either as a phenomenon of *repulsion* against dissimilar neighbours or *attraction* for similar neighbours. From the first point of view  $\tau$  is the *tolerance* against dissimilar while in the second case  $(1 - \tau)$  is the *appeal* for similar. Simulations show that both intolerant and tolerant agents lead the population to segregate with, of course, an *segMix* index higher for intolerant agents (0.952 vs. 0.519) (figure  $\tau\tau$ ). As we use the ER rule, this result confirms the unexpected behaviour provided by the Schelling's model where, in spite of their tolerance, to some extent, agents tend to group together by affinity.

**Micro-Macro congruence** The gap between the threshold of tolerance and the mean utility over the whole population is surprisingly high at the end of a run. If agents are intolerant ( $\tau = 0.375$ ) the congruence between micro and macro levels is close to 0 ( $mM = 0.07$ ); in this way, complex dynamics build much more liveable configurations than necessary. The fact that tolerant agents ( $\tau = 0.625$ ) tend nevertheless to group together by affinity can be explained by a low micro-macro congruence ( $mM = 0.37$ ).

**Frontier** If agents are intolerant, the emerging frontier is essentially built with vacant cells (figure  $\tau\tau$ : white squares). There are many indirect-contacts and homogeneous patterns are isolated by a *no-man's-land* of vacant-cells. As tolerance increases the *no-man's-land* shape becomes more and more complex: as in a real landscape when roughness dictates many meanders to the edge of a lake, the complexity of contours increases (figure  $\tau\tau$ ). We observe that both the *occupancy* and the *porosity* increase with tolerance. So, both the shape and the composition of the frontier change as agents become more and more tolerant.

#### $M_1$ model: repulsion for the unlike

The  $M_1$  model is a variant of the  $M_0$  model where agents are satisfied if the normalized number of dissimilar agent-

(a)  $\tau=0.375$   
 $\text{segMix}=0.952$   $mM=0.07$   
 $\text{occupancy}=0.22$   $\text{porosity}=0.55$

(b)  $\tau=0.625$   
 $\text{segMix}=0.519$   $mM=0.37$   
 $\text{occupancy}=0.69$   $\text{porosity}=0.91$

Figure 1:  **$M_0$  model:** repulsion for the unlike or attraction for the like.

neighbours is below a threshold. So, the threshold  $\tau$  represents the *tolerance* of the agents.

**segregation** The dynamics can be interpreted as a phenomenon of *repulsion* against dissimilar neighbours. Once again, this should lead the system to converge toward a global configuration with segregation. Indeed, we can observe that both intolerance (figure ??) and tolerance (figure ??) lead to segregation. Nevertheless, compared to the  $M_0$  model, the phenomenon of segregation is less marked (table ??); more, if agents are rather tolerant ( $\tau = 0.625$ ), this tendency to group together by affinity is much lower than in the  $M_0$  model ( $\text{segMix} = 0.3$  vs.  $\text{segMix} = 0.519$ ).

**Micro-Macro congruence** For intolerant, as well tolerant, agents the gap between the threshold and the mean utility over the whole population is much lower than in the  $M_0$  model (e.g.  $mM = 0.23$  vs.  $mM = 0.07$ ).

**Frontier** As tolerance increases, there is always a tendency to transform *no-man-land* frontier to *space-fill* curve; but here the frontier occupies more places in the world and its porosity is higher (figure ??).

(a)  $\tau=0.375$   
 $a=0.814$   $m=0.23$   $o=0.40$   $p=0.78$

(b)  $\tau=0.625$   
 $a=0.3$   $m=0.51$   $o=0.88$   $p=0.9$

Figure 2:  **$M_1$  model:** repulsion for the unlike.

### $M_1^*$ model: attraction for the like

As the  $M_1^*$  model is the dual of  $M_1$ , micro-attraction against similar agents-neighbours induces macro-segregation. Indeed, agents are satisfied if the normalized number of similar agents-neighbours is above the threshold: so,  $\tau$  represents the *appeal* of one agent for its similar neighbours. Let's note that the more the *appeal* the more the incentive to move is. As, at the local level, there is *attraction* for the cells which share the same type, once again, this should lead the system to converge toward a global configuration with high segregation. Let's remark that in order to compare the macro behaviour between models  $M_1$  (or  $M_0$ ) and  $M_1^*$ , we have to consider *tolerance*  $\tau$  with *appeal*  $(1 - \tau)$  (e.g. 0.375 vs. 0.625).

**segregation** The emerging segregation can be interpreted as *homophily*, that is the tendency of agents to segregate in spatial groups with similar others. First of all, let's note that the system *converges* towards global satisfaction if  $\tau = 0.375$ ; but, with  $\tau = 0.625$ , it remains forever about 10% of unsatisfied agents in the population; so there is *quasi-convergence* only. As expected, we can observe that high appeal (e.g.  $\tau = 0.625$ ) leads to a strong segregation (e.g.  $\text{segMix} = 0.91$ ) (figure ??); but, more surprisingly, low appeal (e.g.  $\tau = 0.375$ ) leads also to some extend to an

segregate population of agents ( $segMix = 0.567$ ) (figure ??) comparable to what we obtain for the  $M_0$  model with tolerant agents.

**Micro-Macro congruence** For appealing agents the gap between the threshold and the mean utility over the whole population is much lower than in the  $M_0$  model ( $mM = 0.22$  vs.  $mM = 0.07$ ); results are rather comparable to what we obtain for the  $M_1$  dual model ( $mM = 0.22$  vs.  $mM = 0.23$ ).

The fact that agents weakly *attracted* by similar neighbours segregate nevertheless in spatial group with similar others can be explained by a low micro-macro congruence ( $mM = 0.37$ ) comparable to what we obtain for the  $M_0$  model with tolerant agents.

**Frontier** When the strength of attraction towards similar neighbours is high, the frontier have stable properties (i.e. occupancy and porosity are quasi-invariant). Moreover, these properties are comparable to what we obtained with the  $M_0$  model (Table ??). Nevertheless, due to its permanent dynamics, the frontier have now a radically different shape: there is a certain thickness inside which the cells move infinitely (figure ??).

(a)  $\tau=0.375$   
 $a=0.567$   $m=0.47$   $o=0.66$   $p=0.92$

(b)  $\tau=0.625$   
 $a=0.91$   $m=0.22$   $o=0.20$   $p=0.61$   
 $s=90\%$

Figure 3:  $M_1^*$  model: attraction for the like.

## Models of mixing

In this section we consider the models which lead to mixing among the AR models. In these cases it is useless to look at the frontier because, at convergence, this one occupies the world in totality (i.e.  $occupancy \approx 1$ ) and porosity is very high (i.e.  $porosity \approx 0.9$ )

### $\overline{M}_0$ model

In this model agents are satisfied if the proportion of dissimilar neighbours is above  $\tau$  and unsatisfied if the proportion of similar neighbours is below  $\tau$ . Let's remember that this model is self-dual. Because it is the complement of  $M_0$ , macro-mixing is induced either by micro-repulsion against similar neighbours or micro-attraction by the agent-neighbours which share the same type.

**Mixing** We can observe indeed that high value of  $\tau$  leads to a low value of  $-0.53$  for the  $segMix$  index which reveals a strong mixing: the population is mainly an alternation of homogeneous lines or columns constituted by agents with the same type (figure ??). As  $\tau$  decreases, the  $segMix$  index increases too and so mixing decreases (figure ??).

**Micro-Macro congruence** Whatever the threshold is, the gap between the threshold and the mean utility over the whole population is relatively low at the end of a run ( $mM \approx 0.64$ ).

### $\overline{M}_1$ model: attraction for the unlike

In the  $\overline{M}_1$  model agents are satisfied if the normalized number of dissimilar agent-neighbours is above the threshold. Because this model is the complement of  $M_1$ , micro-attraction for dissimilar neighbours will induces macro-mixing.

**Mixing** First of all, let's note that the system *converges* towards global satisfaction if  $\tau = 0.375$ ; but, with  $\tau = 0.625$ , it always remains about 40% of unsatisfied agents in the population; so there is *quasi-convergence* only. In spite of the quasi-convergence phenomena, we can observe that a high value of  $\tau$  leads in the long term to a low value around  $-0.306$  for the  $segMix$  index which reveals mixing: the satisfied agents are then organized as an alternation of homogeneous lines or columns constituted by agents with the same type (figure ??). As  $\tau$  decreases, the  $segMix$  index increases too and so mixing decreases (figure ??).

**Micro-Macro congruence** The gap between the threshold of tolerance and the mean utility over the whole population is surprisingly low at the end of a run (if  $\tau = 0.375$ ,  $mM = 0.73$  and if  $\tau = 0.625$ ,  $mM = 0.96$ ); in this way, complex dynamics build needed liveable configurations only.

(a)  $\tau=0.375$   $a=-0.183$ ,  $m=0.65$ (b)  $\tau=0.625$   $a=-0.53$ ,  $m=0.63$ Figure 4:  $\overline{M}_0$  **model**: attraction for the unlike or repulsion for the like. **$\overline{M}_1^*$  model: repulsion for the like**

In the  $\overline{M}_1^*$  model agents are satisfied if the normalized number of dissimilar neighbours is below the threshold. Because this model is the complement of  $M_1^*$ , micro-repulsion for similar neighbours will induces macro-mixing for low value of  $\tau$ .

**Mixing** Simulations show that the system converges toward a population of satisfied agents where a low value around  $-0.421$  for the *segMix* index reveals a strong mixing: the satisfied agents are mainly organized as an alternation of homogeneous lines or columns constituted by agents with the same type (figure ??). Let's note that the vacant cells are placed at the crossroad between line and column and so allow right or left turns in the structure. As  $\tau$  increases, the *segMix* index increases to a value close to zero and so mixing disappears (figure ??).

**Micro-Macro congruence** There is high congruence between micro-motive and macro behaviour at the end of a run (if  $\tau = 0.375$ ,  $mM = 0.69$  and if  $\tau = 0.625$ ,  $mM = 0.66$ ); in this way, complex dynamics build needed liveable configurations almost only.

(a)  $\tau=0.375$   $a=-0.189$ ,  $mM=0.73$ (b)  $\tau=0.625$   $a=-0.306$ ,  $m=0.96$   $s=60\%$ Figure 5:  $\overline{M}_1$  **model**: attraction for the unlike(a)  $\tau=0.375$   $a=-0.421$ ,  $m=0.69$ (b)  $\tau=0.625$   $a=-0.081$ ,  $m=0.66$ Figure 6:  $\overline{M}_1^*$  **model**: repulsion for the like.

## Discussion and conclusion

Taking inspiration from the Schelling's segregation model, we have proposed a family of models to study the effects of various micro-motives based on attraction or repulsion on the emergence of macro segregation or mixing. Table ?? summarizes results obtained from simulations; all the values are averaged over 100 independent runs.

The *segregate-mixing* index reveals: (i) three expected cases with strong segregation (bold values), (ii) three expected cases with strong mixing (bold values), (iii) two surprising cases with segregation: tolerant agents in the Schelling- $M_0$  model and unappealing agents in the  $M_1^*$  model lead to macro-segregation (underline values), (iv) no unexpected case with mixing.

The *micro-Macro* index reveals: (i) for all the mixing models the micro-macro congruence is high (above 0.6) (ii) for all the segregation models the micro-macro congruence is low (below 0.5) (iii) two extreme cases (bold values): intolerant agents in the  $M_0$  model lead to build much more liveable local configurations than necessary and appealing agents in the  $\overline{M}_1$  model lead to build needed liveable configurations only.

Measuring *occupancy* of frontier reveals that strong segregation comes with low occupancy (bold values).

Measuring *porosity* of frontier reveals: (i) high porosity emerges from tolerant or unappealing agents (bold values), (ii) the lower porosity comes with strong segregation.

We now attempt to provide elements to respond to the issues formulated in introduction.

$Q_1$  Comparison between  $M_0$  and  $M_1$  (or  $\overline{M}_0$  and  $\overline{M}_1$ ) shows that it is not equivalent to flee regarding the *proportion* of dissimilar agents among the neighbourhood agents rather the *number* of dissimilar agents in the full set of neighbours.

$Q_2(a)$  Because  $M_0$  (resp.  $\overline{M}_0$ ) is self-dual, it is equivalent to be attracted by similar (resp. dissimilar) or repulsed by dissimilar (resp. similar) if each one is influenced by the *proportion* of similar among its neighbours.

(b) Because  $M_1$  and  $M_1^*$  (or  $\overline{M}_1$  and  $\overline{M}_1^*$ ) are dual and the respective macro behaviours are different, it is not equivalent to be attracted by similar (resp. dissimilar) rather to be repulsed by dissimilar (resp. similar) neighbours if each one is influenced by the *number* of similar among its neighbours.

## Abstract

Prototype artificial cell models with designed functional molecules are presented here. Artificial molecular devices based on a giant liposome were prepared to obtain specific properties that cannot be obtained from natural cells. In this context, artificial cell research is seen an extension of “molecular robotics” research. Cooperative and integrated chemical systems will be constructed from the molecular devices. Here, we present the 3 aspects of the study model: (1) gene-expressing cell model encapsulated in the liposome to simulate membrane protein synthesis, (2) multirole molecular device with a designed DNA nanostructure on the cellular membrane, and (3) designed membrane peptide device for surface recognition. Although these devices are inspired by living cell functions, such goal-oriented systems are free from the constraints of natural history and evolution. These artificial devices may be integrated to develop novel tools for living systems.

## Introduction

All living organisms are composed of cells, and cells are constructed from various molecules. Since the end of the last century, rapid progress in molecular science and bioengineering has enabled the analysis of complex living phenomena at a molecular level. Such a top-down approach has provided essential pictures of molecular systems, such as the entire human genome, proteome, or metabolome. However, constructive research has also been essential and is already used for evaluating biochemical reaction systems. Such a bottom-up approach also aims to build basic molecular systems from individual molecules. The goal of artificial cell research to create a cell-like structure in a spatiotemporal manner by using a designed molecular system[1]. Several research groups have reported to construct artificial cell models by using liposomes, that encapsulate biochemical reaction networks such as gene expression from a template DNA [2]. In the last decade, synthetic biology has been the main constructive approach, and living cell functions have been modified using standardized genetic components. The establishment of induced pluripotent cells [3] and total synthesis of the bacterial genome [4] are great milestones of this research area.

The goal of the bottom-up and top-down approaches is to construct the entire cell at the molecular level. Such realistic artificial cell studies seek to reproduce the history of the cell at the molecular level and may thus

address the origins of life itself. However, we have also noted the “artificial” aspect of such cell models. It would be possible for the artificial structure in such models to perform a difficult task that is impossible for living cells. Such a capability might contribute to research in a different way from genetically modified cells.

**Fig. 1.** Schematic illustration of a possible artificial cell model consisting of a designed molecular system. We call this system “molecular robotics.”

We are also creating models with designed functional molecules. Such non-natural molecules confer specific properties (e.g., sensing, actuation, and computing) to the artificial cell compartment, which is a liposome. Such artificial molecular devices can be integrated into a complex molecular system to provide a “molecular robot” [5]. In such a context, artificial cell research is included as a subset of molecular robotics (Fig. 1.)

The study model has 3 aspects: (1) a gene-expressing cell model encapsulated in the liposome to enable membrane protein synthesis, (2) a multirole molecular device with a designed DNA nanostructure on the cellular membrane. (3) a designed membrane peptide device for surface recognition. Although these devices are inspired by living cell functions, such goal-oriented systems could become free from the constraints of natural history.

## Gene expression in an artificial cell

**Fig. 2.** Artificial cell model liposomes containing a gene expression system. Upper: Schematic illustration of the system. Lower: The membrane protein connexin was expressed and functioned on the liposome membrane. Liposomes were observed inside cultured cells.

We have constructed a series of artificial cell models based on giant liposomes. A giant liposome is a spherical structure that consists of a closed lipid bilayer membrane, with a diameter greater than several micrometers. The giant liposome membrane is known as the simplest model of the living cell membrane [6]. Several protein synthesis reactions with coupled transcription and translation have been reported by introducing various kinds of functional molecules into liposomes [2, 7, 8]. Expression of functional membrane proteins in the liposome has also been reported in successful [2f, 8, 9]. Connexin-containing liposomes were prepared by using a cell-free transcription/translation system with a plasmid encoding connexin in the presence of liposomes. The nascently expressed membrane protein, connexin, was directly constituted to the liposome membrane on performing in vitro transcription and translation, thus generating pure membrane protein-containing liposomes. The hydrophilic dye calcein or peptides were efficiently transferred from connexin-expressing liposomes to cultured cells (Fig. 2).

One of our future goals in the expansion of this approach is total reconstitution of a living cell. Using extracted cell components from cultured cells, we are trying to completely reconstruct cellular components under conditions approximating those of living cells [10]. We adopt elemental molecular complexes without further processing if they are functional. These approaches may be termed as middle-out approaches. Such studies should indicate how functional components can be managed to obtain a complex life-like system.

## Multirole molecular device based on designed DNA

Recently, DNA has been used as a programmable building material through self-assembly in DNA nanotechnology. Several methods have been proposed for the construction of nanostructures from DNA molecules such as DNA tiles [11], DNA origami [12], and DNA bricks [13]. We can design static nanostructures by using computer-assisted design software (e.g., caDNAno (<http://cadnano.org>)). We designed an artificial molecule that can be used to attach exchangeable molecular devices to the cellular membrane. The X-type body consists of 4 individual single-stranded DNA (ssDNA) molecules with sticky ends, called “ARM sites.” Molecular device attachments are designed to be complementary with ARM-site DNA sequences. The unit called the “ARM” can be attached to the corresponding ARM site of the DNA sticky end.

**Fig. 3.** X-type designed DNA molecules. Upper panel: schematic illustration of the molecular system. Lower panel: X-type DNA equipped with a “tag” was added to living human cultured cells.

The ssDNA sequence was designed for attachment while mixing at room temperature. “Legs” formed from hydrophobic molecules can also be used to attach the DNA body to the cellular membrane (Fig. 3, lower). The DNA body was stained using a “tag” ARM and was thus found to move on the cell surface by two-dimensional diffusion. The diffusion constant was investigated by single-molecular tracking on the cell surface and found to be approximately  $0.3 \mu\text{m}^2/\text{s}$ . The lipid bilayer is a universal molecular structure of the cell, and every receptor is located on a membrane. Similar to membrane proteins, membrane-localized molecular robots (molbots) may be used to control molecular information and compartmentalized conditions inside the cell. Simple molecular robots made of nucleic acids (DNA or RNA) such as those in the present study may be expressed in living cells by genetic engineering. When the molbot was appropriately designed with regard to  $T_m$  (melting temperature of double-stranded DNA or RNA), *in situ* production and function in the desired cell were achieved.

### Designed membrane peptide device for surface recognition

As described in the previous section, nucleic acids such as DNA or RNA are attractive molecules for prototyping of molecular devices. If other types of biomolecules can also be designed easily, they will be useful for the construction of artificial functional cell models. Proteins are the main functional component of organisms and occupy over 16 wt% of the total mass of the human cell.

Compared to DNA nanostructure design, protein design is difficult because protein function depends not only on the linear sequence but also on folding states and post-translational modifications. However, small units of protein, i.e., peptides, can be easily designed and are easy to obtain as commercial molecules. Water-soluble peptides are commonly used as drugs or in the cosmetic field. Here, we aimed to design an artificial sensory molecule for attachment to the liposome. The transmembrane  $\alpha$ -helix domain was designed based on a previous report [14]. A functional metal (Ti)-specific binding domain was prepared using a procedure reported in a previous study [15]. The designed amino acid sequence of the peptide can recognize the specific electrostatic potential of a metal surface and then bind to the surface. The designed amphiphilic peptide was also attached to a fluorescent molecule and mixed with a lipid solution (1 mM DOPC:DMPC:Chol = 6:1:2 with 50 nM peptide) to form a modified liposome with a diameter of 200 nm. The sample solution was placed onto glass with or without a titanium coating. Fluorescence microscopic observation clearly showed that the designed peptide embedded in the liposome membrane could attach to the titanium surface (Fig. 4). Functional designed peptides should also be synthesizable by gene expression in the giant liposome. Construction of a trigger system for expression control (e.g., riboswitches) is awaited.

**Fig. 4.** Surface attachment of artificial liposomes equipped with the designed membrane peptides.

### Conclusion

In this report, we have described our approach for constructing an artificial cell model, that is, encapsulation of biochemical reactants and artificially designed DNA and peptides. However, only combining the functional molecules can never give rise to functional structures; development of the molecular-processing system is a crucial step. If the model is compartmentalized, control of molecular input/output through the membrane is essential. To obtain reliable systems, the transduction mechanism needs to have both noise reduction and signal amplification. Implementation of multiple inputs and multiple outputs coupled with an internal chemical reaction network must also be considered. Given these critical issues, a self-reproducing system is a distant goal. Concerning about an artificial "cell", molecular robotics approach should also support an effort for a cell total reconstitution from natural materials [4, 10, 16]. Currently, undergraduate students have designed bacterial genetic circuits ([http://igem.org/Main\\_Page](http://igem.org/Main_Page)) and DNA nanostructures (<http://biomod.net>). Thus, the current progress in this field indicates that it should be possible to obtain new artificial cell models in the near future.

# Lévy-like Distribution Shown by Intermittent Search Model with Misunderstanding Switch Pattern

Hisashi Murakami<sup>1</sup> and Yukio-Pegio Gunji<sup>1</sup>

hssh415@gmail.com

## Abstract

In an intermittent random search, in which slow motion to detect the target is discretely separated from the motion to migrate to another feeder, the high efficiency of the Lévy strategy is generally found, meaning that the time interval of phase switching is chosen from the Lévy distribution. Though the Lévy strategy is consistent with the searching behavior of real animals, some researchers claim that the Lévy-like distributions exhibited by animals are not necessarily produced by a Lévy process. Here, we propose an intermittent two-phase search model that does not include a Lévy process. In this model, the agent is basically a correlated random walker (CRW), but it memorizes its trajectory and counts the number of crossovers in a trajectory. If the number exceeds a threshold, the agent resets the memory of trajectories and makes ballistic movement in the direction uncorrelated to the past. We also show that this model can optimize the trade-off between macro search (exploration) and micro search (exploitation), which is shown by the CRW. Finally, we demonstrate that another intermittent search model that uses an ambiguous rule to switch the two phases can show a Lévy-like distribution of time intervals.

## Introduction

It is interesting to try to understand how living organisms navigate to targets in a natural environment, where resources are usually unpredictably distributed such that there is limited information about their locations (Viswanathan et al., 2011). The Lévy walk (LW) is considered the most important model of this type of random search, which is a special random walk in which each step length is chosen from a power-law distribution with a heavy tail (a so-called Lévy distribution) (Viswanathan et al., 2008, Reynolds and Rhodes, 2009). The LW shows a scaled step length  $l$  such that  $P(l) \sim l^{-\mu}$  with  $1 < \mu < 3$ , where  $\mu$  represents the power-law exponent. In the foraging simulations, if prey is abundant and, thus, predictable, it is known that classical random walks such as Brownian motion can yield higher encounter rates than LW. In contrast, when preys are sparsely and unpredictably located, LW is more efficient than classical random walks.

In this sense, LW has a reliable theoretical advantage, but is it consistent with empirical data? Indeed, it has been reported that, among diverse organisms, experimental evidence of LW can be found (Humphries et al., 2010, Cole, 1995, Viswanathan et al., 2008). It is most evident in the wandering

albatross. In the first of a series of pioneering works by Viswanathan et al., albatross behavior was tracked by using a humidity sensor attached to one leg of each bird (Viswanathan et al., 1996). Flight-time intervals were measured by wet periods, and dry points were considered to be landings on the water to catch fish. A reinvestigation using GPS, however, showed that most long flights in fact consisted of rest time, when the bird was in its nest, and concluded that there is no power-law distributed step length in wandering albatross (Edwards et al., 2007). Nevertheless, the latest study, which used the same method as above but examined the birds one by one, found that individuals foraging for sparse food exhibited certain Lévy movement patterns eventually (Humphries et al., 2012).

A trajectory of LW describes a search pattern composed of many small step clusters, interspersed by longer relocations known as “saltations” (O’Brien et al., 1990). This pattern can be intuitively described as an intermittent random search strategy in which slow motion is used to detect the target and a discretely separated motion is used to migrate to another feeding location (Bénichou et al., 2011). For example, if we lose a tiny object (e.g., a key) in a huge field, we can consider two simple ways to detect the key: a slow, careful search and a rough, fast one. In the former case, we can search accurately, but we would spend a very long time in the field. In the latter case, we may detect the key quickly, but in many cases, the lack of accuracy would result in just as long of a search time as the slow search. This illustrates a trade-off between the exploitation of old certainties and the exploration of new possibilities, which is frequently found in biology (March, 1991). To balance this dilemma, we would eventually choose a combined strategy, i.e., an intermittent strategy.

In studies of the intermittent strategy, it is difficult to determine the optimal way to switch between the different motions. The Lévy strategy also plays an important role. Bartumeus and his colleague compared a correlated random walk (CRW) (Kareiva and Shigesada, 1983), which is known as a natural way to model the emergence of angular correlations in animal trajectories coming from local scanning, with an intermittent model based on a CRW but incorporating uncorrelated reorientations with a time interval whose length is chosen from the Lévy distribution (Bartumeus and Levin, 2008). Then, they showed that this Lévy intermittent model is more efficient than the non-intermittent version.

Through these theoretical and empirical studies, the Lévy strategy has been established as a key to understanding animal search behavior. Consequently, it has been proposed that the Lévy strategy must be a strong target for natural selection. This is the so-called Lévy foraging hypothesis (Viswanathan et al., 2011). Still, some researchers claim that the Lévy-like distribution shown by animals is not necessarily produced by a Lévy process. Indeed, few models in which an agent walks deterministically and interacts with complex distributed targets can show an LW pattern (Santos et al., 2007). Moreover, Benhamou used combined exponential distributions to suggest that there is no guarantee that a Lévy-like distribution is based on a Lévy process (Benhamou, 2007).

Here, we will show a simple intermittent model that is not based on a Lévy distribution but does possess the principal features of an intermittent strategy, i.e., it shows two different phases. In this model, the number of crossovers in a trajectory is regarded as the extent to which the agent implements local search, and it also represents the threshold used to switch between the two phases. We demonstrate how this model can strike a balance in a trade-off between macro search (exploration) and micro search (exploitation), and we compare the model with a CRW. Finally, we describe another intermittent search model that uses an ambiguous switching rule. The ambiguity results from a stochastically generated long trail, and it generates a search in which the agent wastes too much time. Moreover, we demonstrate that the model can show a Lévy-like distribution of the time intervals.

## Results

### Basic models

First, we present a simple model that includes the main factor of intermittent search, in which an agent iterates to form local scanning behavior (here, we call this the exploitation phase). The local scanning is interspersed by longer relocations or saltations (exploration phase) in continuous space and discrete time. We refer to the entire model as EERW for short.

In the exploitation phase, the agent basically moves as a CRW. Here, angular correlations are introduced on the basis of a circular Gaussian distribution ( $-1.0 \leq g \leq 1.0$ ) centered at the value  $g = 0$  (maximum probability), although other distributions (e.g., a wrapped Cauchy distribution) might be as good (Bartumeus and Levin, 2008). The turning angle is represented by  $\theta = g\pi$ . At each step, the angle of the agent is determined by combining the turning angle with the previous angle. The standard deviation ( $SD$ ) of the Gaussian distribution controls the directional persistence or correlation length of the random walk (Bartumeus et al., 2005, Viswanathan et al., 2005).

In intermittent models, the agents should migrate to another feeder if the local scanning is finished. Hence, in EERW, the number of crossovers in a trajectory represents the extent to which the agent has searched the surrounding area, although switching between phases has usually been implemented by means of a stochastic process such as the Lévy distribution in previous models (Bartumeus and Levin, 2008). In other

words, each agent memorizes its trajectory and counts the number of crossovers in the trajectory. The threshold number of crossovers needed to switch between the two phases is represented by  $NC$ . Note that  $NC$  can be reasonably estimated as the extent of the local search, as we discuss later. If the number of crossovers exceeds the  $NC$  threshold, the agent makes a ballistic movement in a direction uncorrelated to its past, i.e., the turning angle is chosen from a uniform distribution  $\theta \in [-\pi, \pi]$ . Ballistic movement is continued until the time steps are proportional to the steps of the exploitation phase. The longer the agent stays in the exploitation phase, the larger the area searched by agent is, so the agent should spend as much time on local search as it does on relocation. The proportionality constant is represented by  $P$ . Because of its finite memory, the agent resets its memory of the trajectories, returns to the exploitation phase and starts walking again as a CRW at the new location.

The parameters in our model are listed below:

$SD$ : standard deviation of the Gaussian distribution with respect to directional persistence

$NC$ : threshold number of crossovers in a trajectory

$P$ : proportionality constant with respect to distance in the exploration phase

$l$ : step length

In this paper, we fixed the step length at  $l=0.5$ .

Figure 1 Schematic diagram of phase transition in the EERW model: (a) Steps of the Exploitation phase are represented by black arrows, and crossovers are surrounded by blue circles. (b) Steps of the Exploration phase are represented by red arrows, and steps of the previous and following Exploitation phases are represented by dashed and solid black arrows, respectively.

Fig. 1a shows the procedure from exploitation phase to exploration phase. In this case, the agent implements the exploitation phase as a CRW, and its trajectory has three crossovers, i.e.,  $NC = 3$ . When the agent switches to the exploration phase, it makes a ballistic movement comprising three steps, so  $P$  has a value of approximately 0.33 because there are nine steps spent in the exploitation phase.

Fig. 2 shows a series of snapshots of whole trajectories of the CRW and EERW models at  $T = 1000-100000$  with  $SD = 0.3$ ,  $l = 0.5$ ,  $NC = 10$  and  $P = 0.3$ . These simulations are implemented in continuous 2D space with no boundary conditions, but in Fig. 2, they are displayed as if they were in a space of  $200 \times 200$  with a wrapped boundary. It is easy to see that the search area of the EERW is broader than that of the CRW, even though they have the same search steps. In many cases, the agent with the search tasks has a perceptual range with a certain radius, in which the agent can detect a target (Viswanathan et al., 2011). Then, the search efficiency is estimated by the number of targets captured in this range. We may partially regard the search areas as representative of search efficiency. However, if the search area were the most important factor in a random search, it is strange that ballistic movement would be the most optimal strategy. In the next section, we show that EERW can balance a trade-off between macro search (exploration) and micro search (exploitation), which is shown by the CRW.

Figure 2 Snapshot of time development of the trajectories of the CRW (upper side) and EERW (lower side) in a continuous two-dimensional space of  $200 \times 200$  with wrapped boundary condition. Time proceeds from left to right. For both simulations,  $SD = 0.3$  and  $l = 0.5$ , and for EERW,  $NC = 10$  and  $P = 0.3$ . The trajectory of the CRW concentrates and overlaps at the center of the field, whereas that of the EERW is sparsely distributed but covers the entire field.

### A trade-off between macro search and micro search

Biological systems, from individual organisms to groups of animals, are subject to a trade-off between exploitation and exploration at various levels. Especially in open environments, the decision of whether to stay in a known environment or explore a new environment is a difficult one (March, 1991, Gunji et al., 2011, Bénichou et al., 2011). In a random (intermittent) search, the agent would move to another field if the local search were finished. Therefore, the exploitation-exploration dilemma would correspond to the relationship between micro and macro search. In fact, as mentioned above, if the agent moves by means of a strategy leaning toward micro search, it would spend a long time searching a huge field. Moreover, even if the agent detects some targets, those targets cannot be the most abundant resource. On the other hand, if the agent moves by means of a strategy leaning toward macro search, it also takes a long time

to detect targets because of search inaccuracy. Hence, there is a trade-off between micro search and macro search.

In this sense, the classical random walk is the strategy most biased against micro search, whereas ballistic movement is the most biased against macro search. Now, we show that CRW displays a micro-macro search trade-off, because as the parameter  $SD$  approaches zero, the behavior of CRW gets closer to ballistic movement. Conversely, as  $SD$  becomes larger, the behavior approaches a classical random walk. Here, we estimate the extent to which an agent implements micro search by means of the number of total crossovers in a trajectory of 5,000 simulation time steps, and we estimate the extent to which the agent implements macro search by means of closure areas. The closure areas are measured by total neighborhood areas with radii  $r = 1.0$ , where each arrival point of the agent is centered. Overall, the trade-off between micro search, represented by the total number of crossovers, and macro search, represented by the closure areas, is easy to see (Fig. 3). Patterns of CRW are generated with no boundary condition by varying the parameter  $SD$  from 0.01 to 1.0 in increments of 0.01. By comparing the patterns of CRW with those of EERW, we see that EERW can balance exploitation with exploration, and the patterns of EERW are generated under the same conditions as those of CRW, except that  $NC = 15$  and  $P = 0.3$ .

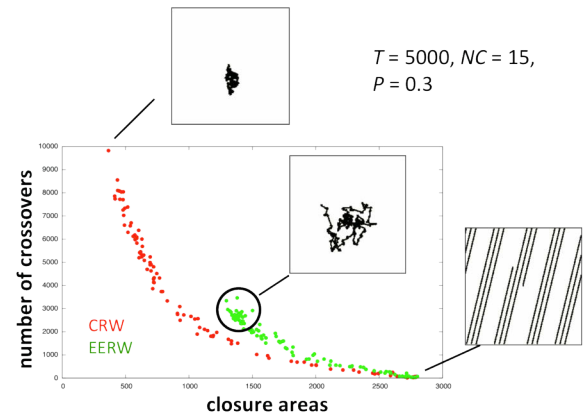

Figure 3 Performance of the CRW (red points) and EERW (green points) with respect to the closure areas and the number of crossovers. Snapshots of trajectories of the CRW with  $SD$  values of 0.0 and 1.0 are represented by top box and bottom box, respectively. Additionally, trajectories of the EERW with  $SD$  0.5 are represented by a box connected to a black circle, which indicates that the EERW can balance the trade-off.

Bartumeus and colleague showed that the Lévy intermittent model could be more efficient than the CRW (Bartumeus and Levin, 2008). In their study, the Lévy intermittent model was compared to the CRW model with two different values of a parameter that controls the directional persistence of the model. However, the CRW can display various behaviors, from persistent, ballistic movement to an uncorrelated classical random walk. We examined the CRW with most of the possible  $SD$  values, revealing that the EERW intermittent model without a Lévy process can balance the trade-off of the

CRW between exploitation and exploration, as calculated by two quantities: number of closure areas and number of crossovers.

### Another intermittent search model

In the study of random search, some models have assumed that agents have memory or learning skills (Ferreira et al., 2012, MacNamara and Houston, 1987). Their memories and learning abilities are also assumed to be finite. However, there has been no attempt to assume ambiguity of memory or misunderstanding of learning. In this section, we first introduce ambiguity and/or misunderstanding in the form of a rule to switch between search phases in the EERW. Second, we show that such a modified EERW (MEERW) results in a Lévy-like distribution of time intervals for phase switching. Finally, we discuss the difference between LW and MEERW.

In the EERW model, the number of crossovers in a trajectory represents the extent to which the agent implements local search. Hence, there was a threshold number of crossovers,  $NS$ , at which the agent switched phases. In contrast, in the MEERW model, which in most ways is the same as the EERW model (Fig. 4a), the value of the threshold  $NS$  is dynamically varied by two types of misunderstanding of the rule.

One such misunderstanding occurs when a long trail is stochastically generated without enough crossovers. We regard it as a ballistic movement (Fig. 4b). If such the long trail is generated, it is assumed that the exploitation phase was already implemented, even though the number of crossovers did not exceed the threshold  $NS$ , and exploration phase is regarded as a trail entailing the reset of the memory of the trajectory. Then,  $NS$  is decremented by one because the agent misunderstands a shorter local search (and the generated trail) as a rule. We here define such a long trail as a series of tracks comprising  $N_t$  tracks, in which the inner product of each track and the next one is greater than  $IP$ .

Figure 4 Schematic diagram of MEERW. (a) The MEERW model is basically same as the EERW, in which  $NC$  indicates how long an agent searches the local area. (b) A long trail stochastically generated decreases  $NC$ . (c) Excessive search time increases  $NC$ .

For the other misunderstanding, we introduce an additional memory restriction: an agent can memorize only  $N_m$  tracks as a trajectory, so it can make crossovers only with the memorized tracks (Fig. 4c). Moreover, if the agent spends  $N_s$  steps without switching phases, then  $NS$  is incremented by one because the agent misunderstands the longer local search as a rule.

In this paper, we fixed the parameters at  $N_t = 15$ ,  $IP = 0.85$ ,  $N_m = 10$  and  $N_s = 100$ .

Now, we demonstrate the Lévy-like distribution of time intervals for phase switching by comparing the EERW and MEERW models. For EERW, we measured the time steps spent in the exploitation phase as the time interval because the ratio of time steps spent in the exploitation phase to those spent in the exploration phase is constant. For MEERW, we basically measure time steps in the same way as for EERW, but if the stochastic long trail is generated, we also measure time steps from the start of the exploitation phase to the time that the trail is generated. Fig. 5 shows the frequency distribution of time intervals in a one million time-step simulation with  $SD = 0.2$  and  $P = 0.3$ . The exponent  $\mu$  is computed as the slope of a regression line for the range of values where power-law behavior (straight line in a log-log plot) is observable. The exponent  $\mu$  for EERW is 5.81 with  $R^2 = 0.957$ . For MEERW, it is 2.38 with  $R^2 = 0.943$ .

In the Lévy strategy with the Lévy intermittent model, the exponent  $\mu$  of the tail of the power-law distribution should be in the interval  $1 < \mu < 3$ . For  $1 \geq \mu$ , the distribution is not defined. For  $\mu \geq 3$ , provided the conditions of the Generalized Central Limit Theorem, the tail converges to a Gaussian distribution. In the latter case, the time interval will show an intrinsic characteristic scale. In this sense, the distribution of MEERW is considered to be Lévy-type but that of EERW is not.

Figure 5 Power-law distributions of EERW and MEERW.

Indeed, the distribution of EERW cannot be Lévy-type. In Table 1, we estimated the exponent  $\mu$  for EERW, varying the

parameter  $NC$  from 1 to 20 and  $SD$  from 0.1 to 0.9. The results show that, for all combinations of  $NC$  and  $SD$ , the exponent  $\mu$  is greater than 3 and has a strong correlation ( $R^2 > 0.9$ ).

		$NC=1$	$NC=10$	$NC=20$
$SD=0.1$	$\mu$	5.472	5.066	4.602
	$R^2$	0.95724	0.92954	0.90619
$SD=0.5$	$\mu$	6.465	6.303	8.426
	$R^2$	0.9613	0.95194	0.93657
$SD=0.9$	$\mu$	7.771	9.071	7.691
	$R^2$	0.94909	0.95885	0.93114

Table 1 Estimation of the exponent  $\mu$  of EERW with the parameters  $NC$  and  $SD$ .

What is the difference between LW and MEERW? It is hard to distinguish the LW model from the MEERW model when we set the step length  $l$  to be very small relative to the parameter  $P$ . Fig. 6 shows a snapshot of a MEERW trajectory with  $l=0.005$  and  $P=3.0$ . It is easy to see that it has the features of an LW trajectory, such as varying step size with some small-step clusters interspersed with longer steps. The main difference between LW and MEERW lies in the behavior exhibited at the arrival point.

Figure 6 Snapshot of a MEERW trajectory with  $l=0.005$  and  $P=3.0$ .

## Discussion

The fact that local clusters are connected by saltations in animal searches and/or LW suggests that there are rules for the detection of targets (Bénichou et al., 2011). The intermittent search strategy assumes that agents move to another field if the local search is finished, which is consistent with the clustering phenomenon. This strategy implies that the agent has two different phases. However, the time interval that elapses before phase switching is given by some stochastic process, such as a Lévy process, rather than a rule.

In this paper, we started with the simple intermittent model EERW, which was not based on a Lévy process but instead was equipped with the principal features of the intermittent strategy (i.e., there were two different phases). In EERW, the

switch between phases is provided as a rule such that, if the number of crossovers exceeds a threshold  $NC$ , the agent resets the memory of trajectories and makes ballistic long trails in a direction uncorrelated with the past. We demonstrated that EERW could balance a trade-off between macro search (exploration) and micro search (exploitation), and we compared the EERW model with a CRW.

Finally, we constructed a MEERW by incorporating ambiguity or misunderstanding of the rule, in which a threshold  $NC$  is dynamically varied by the stochastically generated long trail and excessive search times. As a result, MEERW showed Lévy-like distribution. Moreover, depending on the parameter values  $l$  and  $P$ , MEERW could behave much like an LW model.

An LW model has already been constructed without a Lévy process, yet there must have been deterministic walks and interactions with a complex distribution of targets (Santos et al., 2007). Thus, our model is the first attempt to investigate the hypothesis that an LW can be generated in the absence of a Lévy process and without deterministic walks.

## Abstract

We are interested in understanding how conflicts for common resources can be resolved when concurrently selfish agents are in place. To answer this question, we investigate a many-core machine that performs concurrent operations. Even with the selfish and non-cooperative nature of computational processes, they successfully organize a whole task. More specifically, we use the almost lock-free (ALF) architecture, which enables effective concurrent computation on a many-core machine. A unique point of the ALF is that it performs operations on shared resources simultaneously without excluding each other. We conducted data management experiments by varying the different number of cores on a single machine and investigating the characteristic dynamics of when the highest performance is observed. We found that the temporal dynamics of the number of operations changes from noisy to bursty pattern at the optimal point. In other words, the optimal computation is found at the edge of chaos. We argue that species or agents that interact concurrently with others show chaotic behavior in a congestion state, and the cooperative state is established in the chaotic state.

## Introduction

From multi-cellular organisms to swarms of birds and a large ecological system, there is a conflict for common resources, e.g., food, territories, etc. This type of conflict can be resolved by introducing temporal oscillation. When  $N$  number of agents can periodically access the resource in turn, a happy solution can be obtained where everybody can share an equal amount of the source. This periodic behavior is realized as turn-taking behaviors (Iizuka and Ikegami, 2004; Ikegami and Iizuka, 2007). Or the conflict can be resolved spatially by each agent sticking to its own niche (i.e., food/territory) without invading space belonging to others. This spatial division of niche is often observed in ecological system and other social systems.

But what happens if agents become selfish and access the resource at a time or invade the other niche? Does it always end up with an unhappy solution where

nobody gets anything? Is it always bad manners to steal another's niche? In this paper, we investigate an artificial system that performs concurrent operations on many cores to answer these questions. More specifically, we are interested in understanding how parallel processing threads cooperatively work together and organize an entire task. We tackle this problem by having a new computational framework called "almost lock-free" (ALF for short), where we let each thread access a common work space without completely prohibiting others to access the same work space at the same time. A small interfering behavior will lead to an optimal behavior as we will show below.

ALF, presented here is a new algorithm we have invented for processing data concurrently in a computer with many cores (Wei and Kato, 2013). Due to the selfish and non-cooperative nature of computational processes, it usually is difficult to increase the throughput when performing concurrent operations on many cores. This is because, in order to maintain consistency of computation, *lock-operations* should be performed every time an operation accesses the common workspace. However, these lock operations become overhead and throughput decreases. Thus, when dealing with concurrent operations or multi-threading computation on many cores, how to process *lock-operations* are important factors to consider for achieving high throughput. ALF deals with this issue by permitting the mutual interference among processors. Using the ALF system, we will observe how concurrency causes congestions or conflicts, as well as how mutual cooperation emerges in such a system.

## Almost Lock-Free System

One of the remarkable developments of processor industry in the last decade is the serial processing speed

Figure 1: (a) An example of how B-tree (of order 2) is constructed. (b) An example of a large B-tree (of order 4) with randomly distributed key values. Colored space indicates the keys are inserted and uncolored space indicates the free space. Red node indicates the triggers of split. (c) An example of a large B-tree (of order 4) with ordered distributed key values.

or clock rate of core. Today, a standard computer is equipped with multi-core or even many-core processors. To make full use of these processors, concurrency control approaches have been proposed for writing concurrent programs. Dominant concurrency control approaches take what is called a pessimistic approach in which locks are performed every time a thread accesses the shared space. However, this extensive lock-based approach limits the concurrency of operations on multi-cores.

On the other hand, optimistic concurrency control approaches have been proposed. The optimistic approach assumes that multiple operations can complete without affecting each other. When conflict happens, the committed operations roll back. The optimistic approach can achieve a high throughput when conflicts are rare, since operations can complete without the expense of managing locks and without having operations wait for other operations' lock to clear. However, if conflicts happen often, the cost of restarting operations hurts performance significantly. ALF takes an approach that combines the pessimistic and optimistic concurrency control approaches, which we will explain in more detail below.

### Balanced Tree Data Structure

Many different types of file systems exist such as HFS for Mac OS, Ext for Linux, NTFS for Windows machines, ISO 9660 used on DVDs and CDs and so on. They are different in directory structure, how much spaces files are allowed to use, what sort of metadata

(about the usual data) is managed. But the basic purpose and architecture of modern file systems are similar to each other. In general, their purposes are managing access to the content of both data and the meta-data available on local and global storage devices. In particular, a data structure called *balanced Tree* (B-tree for short) is used for organizing the indices in current file systems for efficiency; B-tree supports operations such as searches, insertions, and deletions in logarithmic time efficiency. ALF uses this B-tree data structure for managing concurrent operations.

B-tree is constrained to have an equal number of pointing nodes per each node in a data-address tree. A dynamic way of constructing B-Tree under this constraint provides a unique growth of the tree form. For example, Figure 1 shows how a B-Tree grows for an input sequence of key values (40, 15, 5, 10, 12). In the example, each node can contain two values, or order of 2. A value is inserted into a node in an ascending order until the node becomes full (step 1 to 3). When the node is full, it creates two child nodes as depicted in step 4 taking the median as the parent node. Then it continues to add a value to the tree in an ascending order. It happens that the tree becomes unbalanced as in the case of step 5. When this happens, the tree adjusts itself to make it balanced by moving an adequate value to its parent node as depicted in step 6. The nodes at the bottom of the tree are called *leaf nodes* and the other nodes are called *internal nodes*.

Properties on B-tree have been extensively studied

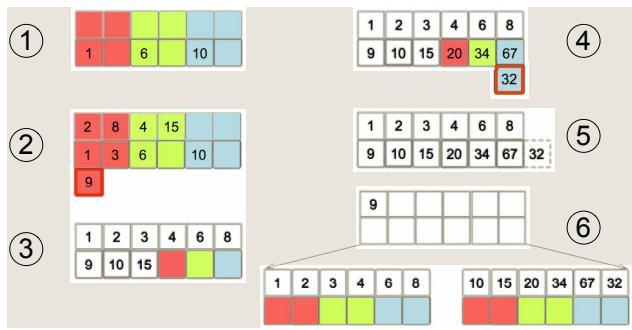

Figure 2: An example of how B-tree (of order 12) grows using ALF with three threads.

in the literature and the best-known property of B-tree is that it uses  $\log_e(2) = 69\%$  of spaces in each node when randomly distributed keys are inserted in B-tree (Johnson and Dennis, 1989). Examples of large B-trees are shown in Figure 1-(b) and -(c), with randomly distributed keys insertion and with sorted keys, respectively. These large B-trees show how leaf nodes are added or split with time. ALF uses this B-tree data structure for managing concurrent operations (i.e., insertion, deletion and searches).

### ALF on B-tree

ALF takes a hybrid approach which combines optimistic and pessimistic concurrency controls on a B-tree data structure. More precisely, ALF operates on optimistic concurrency control and only executes locks when a certain condition is met. This may cause inconsistency during the data management processes. ALF achieves this by modifying the node in the data structure and allows many threads to update the same leaf node simultaneously. A key feature to combine optimistic concept with pessimistic concurrency controls is that it gives a minimum modification for tree node structures and concurrency controls. The concept of ALF is not just about managing the data, but it also tells us how each agent should behave independently and cooperatively with a common resource.

More practically, data structure is divided into two types, *public space* and *private space*. Each core operates on private space and interacts with each other through the public space. Since operations conducted on private space are not shared on the public space, other cores cannot see even if some operations can cause conflicts on the public space. For example, an

insert operation conducted on a private space is not recognized by other cores until data is merged in the public space. If we lock the public space every time an operation affects the public space, or if we have a global clock, this conflict can be avoided.

Instead, ALF does not perform the lock every time an operation is performed on the public space, but rather lets it run until a certain condition is met, allowing some inconsistency in the data to occur. Without a global clock or complete lock operation, one may expect that the system will not self-organize anything due to the conflicts among private cores. Here we will show that this is not quite the case but rather it shows better throughput.

Figure 2 shows an example of how a B-tree grows with ALF. Here we take three threads as an example. Each thread corresponds to a core. The tree node structure is divided into two areas; the public space and the private space. The ALF adopts the idea of a thread-local area where threads can write to the private area simultaneously, to achieve a partial lock-free status. The data in the private space will be reflected on the public space by using exclusive locks when the private space becomes full. This operation is called **reorganization** and it happens when the private space for one thread becomes full. This reorganization phase is the only lock phase in the approach, and thus it is called almost lock-free.

Here, we explain how ALF works on B-tree (of order 12) by following the steps depicted in Figure 2. The initial node is assigned to private spaces and the same amount of space is allocated for each thread. Thread 1 is colored in red, thread 2 is colored in yellow and thread 3 is colored in blue, respectively. In this example, we only consider *insert* operations. We explain each step below.

- 1) Keys 1 (thread 1), 6 (thread 2), and 10 (thread 3) are inserted in each private region.
- 2) When the key 9 is assigned to thread 1 after inserting the key 2 in the same thread, it detects that the private space for thread 1 is full. This triggers reorganization of the node.
- 3) When reorganization is triggered, all the operations in the private area are reflected on the public area and keys are inserted in the public area in an ascending order. The remaining space is distributed equally for each thread.
- 4) Keys 20 (thread 1), 34 (thread 2), 67 and 32 (thread 3) are inserted on the private area. When the key 32 is inserted in thread 3, it triggers the reorganization again.

Figure 3: Throughput (number of operations executed per millisecond) when varying the number of cores and the orders.

- 5) All the keys in the private regions are inserted into the public area. However, the public area does not have enough space for all the keys in the private area. This triggers the node to split.
- 6) The medium key is taken as a parent node and two children nodes are created.

Note that private spaces are only allocated at the leaf nodes and all the internal nodes are allocated as public spaces.

### Experiments

We conducted experiments using the ALF on 64-cores machine. Here, we only use insertion as operation. The total number of keys which are randomly manipulated is 1,000,000 of the range  $[0, 1000000)$ . The order (i.e., the node size) is set to 100, 150, 200, 250 and 300. We measure the total execution time on manipulating million keys by invoking system call <sup>1</sup>, and then calculate the throughput (= number of operations per millisecond).

#### Best Degrees of “almost”?

Figure 3 shows the results of the throughput. The average throughput of the five runs is depicted in the figure. We see that the optimal throughput is obtained when the number of cores is 16 for all the orders and it decreases after that. This is because, although we gain a lot of concurrency, when the number of threads becomes larger, it also triggers a lot of reorganizations

<sup>1</sup>The system call named CLOCK\_GETTIME is used.

Figure 4: Total number of reorganizations and throughput with different number of cores. The throughput is maximized at 16 cores and after that the throughput decreases as the number of reorganizations increases.

and thus leads to decrease in throughput. For example, in the case of 64 cores with the order of 150, only 2 or 3 spaces are allocated for each thread; resulting in the large number of reorganizations to occur. This is confirmed in the Figure 4, which plots the number of reorganizations and the throughput in relation to the number of cores (the order is set to 150). The number of reorganizations increases as the number of cores grows.

### Characteristic Dynamics of ALF

A characteristic feature of ALF, comparing with the extensive locking system, is that a larger number of reorganizations on B-tree can occur at a time as the number of threads becomes larger. The reorganization occurs when no space exists for executing operations on any thread in the private space.

Figure 5 shows the time evolution of the internal nodes and the free space ratio at each reorganization. Characteristic dynamics is observed in the stepwise increases of the number of internal nodes. The reorganization makes new space for each thread to execute the operations and the number of free space will increase following the number of internal nodes of a tree. Having too many cores leads to frequent reorganization, slowing down the entire performance.

On the other hand, if it has enough space, many cores can work concurrently, increasing the entire perfor-

Figure 5: Dynamics of changes in the ratio of the free space in the entire B-tree and the increase in the number of internal nodes.

mance. As we saw in Figure 3, the maximum throughput is found around when the number of core equals to 16. If operation load is equally balanced among concurrently processing threads, the number of possible operations should be proportional to the number of cores. But actually, unbalanced operational loads occur that suppresses the number of operations resulting in the decrease of throughput.

In Figure 6, the number of leafs and internal nodes develop differently in time depending on the number of cores. For the number of cores equal to 4, the number of leafs shows a convex curve, whereas that of 64 shows the concave and that of 16 is hybrid. For the number of internal nodes, all the examples show step-wise development, except that the case of the number of cores equals to 16, the step size does not grow geometrically, but rather with some modulations. These are the pieces of circumstantial evidences that the core number equal to 16 is at the boundary of two quantitatively different dynamics phases.

The singularity of the core = 16 is also reflected in the time evolution of the free space ratio and the number of operations. Figure 7 shows the dynamics of the number of operations and the ratio of free space of the entire B-tree. The leftmost figure corresponds to the single core case, and the right most figure corresponds to the case with 64-cores. When the number of cores is below 16, the possible number of operations over a course of time is suppressed at a lower value around 100. By further increasing the number of cores, the

(a) cores = 4

(b) cores = 16

(c) cores = 64

Figure 6: Time evolution of the total number of leaf nodes and internal nodes of the B-tree. The red colored line shows the total number of internal nodes and the blue colored line shows the total number of leaf nodes.

number of operations will be raised to around 500 with bursty time series. The critical core number 16 corresponds to the transition point. To confirm this transition, we counted the number of local peaks in the time series of the number of operations 8. We superimpose all the extracted peak values by changing the number of cores. We can observe a quantitative transition when the number of cores is 16.

We can summarize the behavior of the number of operations and of free space as follows.

- i) The number of operations can be classified into two patterns: a noisy time series with lower amplitudes and a bursty time series with larger amplitudes. The

Figure 7: Dynamics of the number of operations and the ratio of free space of the entire B-tree. The figures are shown for cores = 1, 2, 4, 8, 16, 24, 32, 40, 48, 56, and 64 from left to right. The optimal throughput is found at core = 16 and is colored in grey.

optimal throughput (core = 16) is found at the transition point of these patterns. An exception is the single-core case whose time evolution of operations is similar to the optimal case.

- ii) The number of free space on average is proportional to logarithm of the number of cores.

Figure 8: Counting the number of local peaks in the time series of the number of operations, we superimpose all the extracted peak values (y-axis) by changing the number of cores (x-axis). It should be noted that there is a qualitative transition at the number of cores equals to 16 (colored in red).

From these observations, we say that the optimal number of cores for the entire computation is found at the transition point, which is at the edge of the chaotic state and the bursty phase.

### Discussions

We know several examples showing that the optimal behavior can be found at the edge of chaos. This paper adds another example that the optimal computation is found at the edge of chaos and the bursty behavior. In our previous work, we have also found that the optimal

throughput of the packet switching network (PSN) at the edge of chaos and the periodic window (Ikegami et al., 2011; Takayasu, 2005). In the case of PSN, congestion of packets occurs at the critical point where the throughput becomes optimal. In an analogy with PSN, we hypothesize that congestion among different threads allows the system to perform more operations.

Concurrency causes congestion and congestion lets a system rearrange the B-tree structure, creating more free space. That is, with the increase in the size of free space, effective competition among threads is suppressed. In other words, a mutual cooperation emerges. A juxtaposition of three unrelated C-terms, concurrency, congestion and cooperation is linked by the dynamics at the edge of chaos.

A similar discussion can be applied to an ecological system's dynamics. Host and parasite networks organize a complex food web. With respect to the population dynamics of each species dynamics, we know that a weak chaos with large degrees of freedom, called *homeochaos* (Kaneko and Ikegami, 1992) leads to a network symbiotic state (i.e., cooperative phenomena). This chaotic state is attained by auto-tuning dynamics of mutation rates of each species. An initial set of species self-organizes into this homeo-chaotic state by increasing the mutation rates.

We believe that the biodiversity of a rainforest provides such an example. The abundance of each species in a rainforest is relatively low but many different species can co-exist in the same place (Connell, 1978). We argue that congestion of species produces chaotic dynamics in an ecosystem and they work concurrently. That is, species or agents that interact concurrently with others will show chaotic behavior in a congestion state, and the cooperative state is established in the chaotic state. The current work provides that the same principle can be applied in a concurrent computing system.

## Conclusion

We proposed a new idea of effective concurrent computation without using the scheme of extensively locking. A unique point of this scheme is that all the threads perform operations simultaneously without excluding each other. We found that the optimal number of cores for efficient computation is 16 in our experimental setting. The temporal dynamics of the number of operations changes from noisy to bursty pattern at the optimal point. We thus insist that the optimal computation is found at the edge of chaos. The emergence of this critical point comes from the almost lock scheme.

## Abstract

To operate in dynamic environments robots must be able to adapt their behaviour to meet the challenges that these pose while being constrained by their physical and computational limitation. In this paper we continue our study into using biologically inspired epigenetic adaptation through hormone modulation as a way to accommodate the needed flexibility in robots' behaviour, focusing on problems of temporal dynamics. We have specifically framed our study in three variants of dynamic three-resource action selection environment. The challenges posed by these environments include: moving resources, temporal and increasing unavailability of resources, and cyclic changes in type and availability of resources related to cyclic environmental changes.

## Introduction

In autonomous robotics, there is still a trend to develop and tune controllers with certain explicit goals and environments in mind (see e.g., Suganöl & Shirai, 2006; Krichmar, 2012 for an overview). This tuning can be either very direct such as pre-determining the weighting of environmental cues, or more subtle through the use of mechanisms such as reward feedback, fitness functions and activity functions (Krichmar, 2012; Lones & Cañamero, 2013).

However, even slight changes in the environment can lead to significant and often unpredictable changes in the trajectory of the same behaviour (Simon, 1969; Braitenberg, 1984; Steels, 1994; Maris & Boekhorst 1996). While environmental changes tend to modify the organism's behaviour in relation to the environmental change (see e.g., Clemens et al., 1978; Crew, 2010; Zhang & Ho, 2011), significant changes to the environment of robots possessing pre-programmed/determined adaptation mechanisms can lead to behaviours that are not only unsuitable but may render the robot inoperable (Tschacher & Dauwalder, 1999; Krichmar, 2012; Lones & Cañamero 2013).

Biological organisms are able to cope with environmental change through long-term evolutionary adaptation, more rapid ontogenetic adaptation, or through learning (Wilson et al, 1994; Cacioppo et al., 2002; Carere et al., 2005). In organisms, a form of epigenetic development occurs through

interactions with uncertain and dynamic environments (Jaenisch & Bird, 2003; Carere et al., 2005). These interactions can lead to changes in gene expression (Fowden & Forhead, 2011; Zhang & Ho, 2011) and subsequently to the appearance of new behaviours (Crews, 2011) adapted to a specific ecological niche (Narain, 2012). Recent studies have shown that hormones provide some of the signals needed to trigger the development of different aspects of the organism (Clemens et al., 1998; Crews, 2010; Fowden & Forhead, 2011).

In past experiments (Lones and Cañamero, 2013) we tested the viability of using epigenetic hormone modulation as a way to allow a robot to adapt to unknown environments. In that study, we placed the same architecture into various environments posing different challenges to the robot. For each experiment, we researched the ability of the epigenetic robot to develop unique behaviours in direct relation to the environmental challenges. In all cases, a significant increase in viability was noticed in the epigenetic model compared to an architecture lacking the epigenetic mechanism.

In the present study, we investigate the ability of a robot, endowed with the same architecture as in the above-mentioned study, to cope with environments posing different types of temporal dynamics problems. In our previous study, the environment we used, while possessing some dynamic qualities, were predominantly static. Changes in that environment occurred as a consequence of the robot's actions. However, in this study, each environment has its own dynamics. This creates an opportunity to examine the robot's behaviour when faced with constantly changing and potentially unpredictable environments.

## Robotics model

**The robot** we have used in this study is the Koala II ([www.k-team.com](http://www.k-team.com)), a medium-sized wheeled robot. It is equipped with 16 infrared (IR) sensors placed around its body, and we use them as both proximity sensors and touch sensors. Proximity IR sensors are grouped to monitor the eight cardinal and ordinal directions surrounding the robot. In our case, this permits the detection of the direction that possesses the least resistance to movement. Touch IR sensors "extend" the

robot's body by 1cm—what we refer to as “extended body”. Any encroachment of this area is categorised as contact, and the force of contact is dependent upon both velocity and persistence of the encroachment. Finally, we have fitted a webcam to the robot that, in combination with OpenCV, allows the robot to track specific coloured objects. For a more detailed overview of our setup please see (Lones and Cañamero, 2013).

**The Physiology** of the robot consists of three survival-related homeostatic variables, which must be maintained within a pre-set boundary ( $0 \leq h.var_i \leq 100$ ) for continued survival (see table 1). These three survival-related homeostatic variables are based upon plausible robotic needs in form of energy (E), physical condition (C) and temperature (T).

The robot's *energy* depletes at a rate equivalent to a basal metabolic rate plus the energy cost of activating subsystems such as vision. Since these subsystems are always active in this implementation, energy decreases at a constant rate of  $\delta$  per step. *Condition* represents a measure of health for the robot. Deficits occur in a semi-unpredictable manner from collisions. Both variables can be recovered by finding and consuming specific resources. Finally, *temperature* represents the internal heat level of the robot. The robot's temperature rises as a function of a combination of the environment's ambient temperature and the robot's movement speed. Cooling down (dissipation of temperature) occurs at a constant rate. Assuming a moderate or rapid dissipation of excess heat, the robot is able to maintain a steady speed without running the risk of overheating. Table 1 provides an overview of the different internal variables.

H.Var	Ideal Value	Limit	Cause of deficit	Recover per step
E	100	0	$\delta = 0.1 \downarrow$	$1 \uparrow^*$
C	100	0	Contact $\downarrow$	$1 \uparrow^*$
T	0	100	Movement $\uparrow$	$0.8 \downarrow$

\* The robot must be near the resource for recovery to commence

Table 1: The homeostatic variables of the robot. In this implementation, if Energy or Condition fall below 0, the robot “dies”. Temperature has an inverse effect.

These survival-related homeostatic variables give rise to a Viability zone (Physiological space), following Ashby (1952) and Avila-García and Cañamero (2004). The position in and management of the dynamics of the viability zone provide different ways to quantitatively measure the robot's performance and wellbeing. Like Avila-García and Cañamero (2003, 2004) and our earlier paper Lones and Cañamero (2013) we have used this idea of the viability zone to create a performance indicator called “comfort”. Comfort provides a measure of the average homeostatic deficit at any time, and the “risk of death”, which indicates how close the internal state is from reaching lethal values. Comfort is calculated on a scale of 0 to 1; with a comfort level close 1 indicating homeostatic variables near their ideal levels. Whereas a comfort level near to 0 would indicate large homeostatic deficits and a high “risk of death”. Along with the comfort

level the standard deviation at specific points is also provided. This allows for a greater insight into the robot's performance.

## Hormones

Apart from providing a measure of wellbeing, the tendency to satisfy homeostatic needs provides part of the foundation for the formulation of motivations. Internal needs modelled as homeostatic variables have long been used to model motivations in robotics, providing efficient and understandable simple models that permit the generation of appropriate goal-oriented movements and behaviours (e.g., Cañamero, 1997; Breazeal & Scassellati, 1999; Arkin, 2003; Bach, 2011). However, in biological systems matters are more complex, as motivations do not come directly from homeostatic deficits. Rather, hormone secretion derived from homeostatic deficits (e.g., ghrelin in the case of hunger) are shown to be behind the formation of motivation (Wallen, 2001; Malik et al., 2008) and the motivational value of environmental cues (Wied, 1976; Martinez, 1981; Frijda 1986). The development of an organism's hormonal gland activity (in the form of synthesis and release) as well as the development of receptor sensitivity are believed to be susceptible to both endogenous and exogenous environmental cues (Zhang & Ho, 2011). This would suggest that motivation is also in part affected by past experience.

An epigenetic hormonal motivation-like system could potentially provide an efficient method to allow robots to align their needs and goals with challenging environments on a more permanent basis, e.g., to “grow up” adapted to an environment presenting uneven opportunities to fulfil survival-related needs. This process would affect the tolerance to different homeostatic deficits and the priority with which they would be maintained as a function of the developmental environment. Through such an epigenetic process, during the earlier stages of the development of the robot, its hormone glands associated with underrepresented needs would become more sensitive. That is, smaller homeostatic deficits would trigger the same level of hormone secretion as we would see in robots that had “grown up” in a more balanced environment.

Hormones are however not limited to motivations. In our previous study (Lones and Cañamero 2013), we showed how an epigenetic hormone-like system can give rise to diverse behaviours tailored to different environments. While hormone-modulated behaviours had already been successfully modelled in the past, what sets our model apart from others such as (Avila-García and Cañamero, 2004; and Krichmar, 2012), is that: (a) instead of having a limited number of pre-set behaviours, behaviours emerge from the combination of the hormone-activated sub-systems within the robot; and (b) that due to the epigenetic nature of the hormone glands, this means that two robots with the same motivational tendency but with different developmental histories may behave in different ways.

## The Action selection mechanism

The ASM incorporated a “voting-based” (VB) policy based upon ideas presented by Tyrell (1993). By using the VB architecture, actions selected by the robot will be those that

provide the greatest overall benefit. In comparison, a “winner-takes-all” (WTA) policy would lead to the selection of the actions that satisfy the current greatest need. Although Avila-García et al. (2003) found that a WTA outperformed the VB architectures in dynamic environments, in their environments the dynamics was introduced by the presence of predators, thus posing very different challenges. Using our model, in preliminary experiments we found that the VB architecture performed better, as shown in figure 1. These preliminary experiments consisted of five 5-minute runs of each architecture type. Performance was measured using comfort as an indication of the robot’s wellbeing.

Figure 1: Comparison of the performance of VB and WTA architectures.

### Hormone System

At the core of the VB ASM lies a hormone-like system influenced by models developed by Avila-García & Cañamero (2004) and Krichmar (2012). In a new development, we have implemented two different types of hormone, which are classed as either endocrine hormones (Eh) or neurohormones (Nh) (see Table 2). Drawing on biological systems, our Eh-like implementation consists of hormones with the primary purpose to try to maintain homeostasis (Murphy & Bloom 2006). The Eh group is made up of three hormones: one associated with each homeostatic variable. For each hormone,  $h$ , secretion occurs via a gland,  $g_h$ , and the rate of secretion,  $s_h$ , depends upon the current homeostatic deficit,  $d_h$ , and the activity level of the gland,  $\Psi_h$ ,

$$s_h = k(\Psi_h^{d_h}) \quad (1)$$

where  $k$  is a constant that scales the size of secretion. Once released, each secretion persists in the system for a random number of action loops (within a fixed range) before decay of that particular secretion occurs. The larger the secretion, the longer it will take to fully decay. The concentration ( $conc_h$ ) of these hormones is thus determined by the total sum of each active secretion.

The second group of hormones, Nh, contains only one hormone, D1. This hormone facilitates what can be described as “dominant” or potential “aggressive” behaviour. This is achieved by having the hormone suppresses environmental cues that are associated with negative stimuli. For example a robot with a high D1 level that detects a desired resource will move towards it directly at a high speed pushing aside any obstacles, disregarding the potential of damage from

collisions. In contrast a robot in the same situation but with a low D1 level would instead move around obstacles to reach the desired location.

Rather than being triggered by internal deficits, as with Eh hormones, Nh secretion is linked to the mean of the external environmental cues ( $ec_{dt}$  where  $d$  is the direction of the cue and  $t$  the type e.g. energy or repair source). Therefore the  $conc_h$  of the neurohormone is determined by

$$conc_h = (conc_h\beta) + \alpha\bar{ec}\Psi_h \quad (2)$$

where  $\alpha$  is a predetermined weighting factor ( $0 \leq \alpha \leq 1$ ) and  $\beta$  is the disperses rate of the hormone which is set to 0.9 (leading to a 10% disperse rate each loop) during these experiments.

Also different to the Eh model,  $\Psi_h$  is not a set value. Instead, the activity level of the gland is stimulated by the mean concentration of the Eh hormones ( $conc_{Eh}$ ) in the body, similar to tropic hormones. Where in biological systems, these hormones have been demonstrated to cause/increase the secretion/production of other hormones (Sherwood, 2003):

$$\Psi_h = e^{-4e^{-0.5conc_{Eh}}} \quad (3)$$

$\Psi_{D1}$  will lie between a value of 0 and 1, with a value of 1 indicating the gland is fully active, and 0 signifying that the gland is inactive. The final part of the Nh equation models neuroreceptor sensitivity ( $sen_h$ ).

$$streng_h = e^{de \times e^{sen_h conc_h}} \quad (4)$$

where  $streng_h$  the cumulative effect of the neurohormone on the system once the concentration and sensitivity to it are taken into account,  $de$  is the minimum stimulation needed for activation of the receptor, and  $sen_h$  the sensitivity of the receptor to the hormone.

H. Name	H. Type	Trigger	$\Psi_h$
E1	Eh	Energy deficit	0.09
C1	Eh	Cond deficit	
T1	Eh	Temp deficit	
D1	Nh	Visual cues	Varies

Table 2: Robotic hormones

### Hormones and the ASM

The VB ASM consists of a two-step computation (see figure 2). The first step calculates the current homeostatic motivations or drives ( $m_{dt}$ ) (see Table 3). Although three drives are present, we only need to directly calculate the intensity of hunger and damage. The hyperthermia drive, which can be satisfied by reduced or no movement, instead suppresses other drives. In addition to the internal state, motivations are influenced by environmental cues,

$$m_{dt} = \begin{cases} \frac{conc_h(t)ec_{dt}}{1+conc_{T1}} & \text{if } strength_{D1} > 0.75 \times conc_{T1} \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

The perceived environmental cue in the forward direction,  $ec_{2t}$ , is given an additional +1 score to simulate a restless mechanism and allow forward movement without external stimuli. To further reduce excessive switching of motivations  $ec_{2t}$  is given a 10% bonus to its value as a form of “hysteresis”.

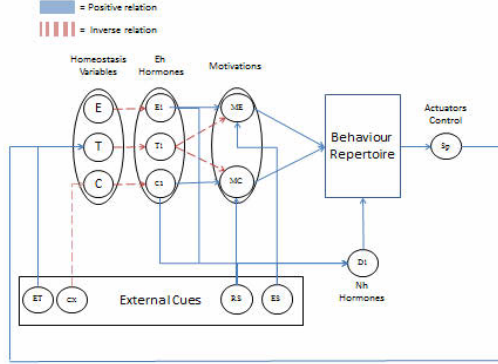

Figure 2: Hormone-based Architecture.

Motivation	Drive	ext Stimuli	Suppressed by
Hunger (ME)	E1	Eng source	T1
Damage (MC)	C1	Rep source	T1
Hyperthermia	T1	Climate	E1 & C1

Table 3: Motivations of the robot

The second step in the ASM calculates the behaviour to execute given the current motivational state and environmental conditions. Unlike previous hormone-based architectures such as Avila-García & Cañamero (2004) and Krichmar (2012) no explicit behaviours have been modelled. In our case, behaviours occur from dynamic combinations of different systems with no pre-set physiological cost or gain. The cost or gain of behaviour execution results from the sum of physiological changes that occurred during the action.

One of these subsystems is the robot’s personal space (Ps) (see Hall, 1966), an area that the robot will treat almost as an extension of its own body. Using a similar technique as with the “extended body” (the IR-based touch sensors around the robot’s body), the robot will normally maintain the Ps free from other objects. The radius of the Ps zone is determined by the current C1 hormone concentration. Encroachment will lead to attempts to re-establish a space by moving along the path of least resistance ( $d_n$ ), with a slight preference to going forward. D1 counteracts the tendency to keep the Ps empty, allowing objects within the Ps while trying to satiate drives. At high levels D1 will facilitate physical contact, allowing the robot to push or “attack” anything standing between itself and its target, the size of the Ps at any given time is show in equation 6.

$$Ps = \left( ns + ns \frac{conc_{C1}}{conc_{C1\{max\}}} \right) (1 - strength_{D1}) \quad (6)$$

where  $ns$  is the normal, unadjusted size of personal space, and  $conc_{C1\{max\}}$  the maximum potential concentration of the hormone.

## Hormone-Signalled Epigenetics

The final and following aspect of the model introduces an epigenetic adaptation mechanism into the architecture. Taking inspiration from recent biological studies (see Crews, 2008 & 2010, Fowden & Forhead, 2011 for an overview) hormones trigger epigenetic changes in the robot. In our robot, hormone levels both indirectly and directly provides a fairly accurate measure of current conditions in the environment and level of situatedness. For instance, the current level of the E1 hormone is an indication of how well the robot is managing its need for energy. Combined with the concentration of D1, it is possible to determine the root of the imbalance, as either issue of scarcity, or difficulty of access to the resources.

These hormones can thus act as signals for epigenetic adaptation, whereby development of the glands that secrete hormones and receptors that receive them are influenced by the external environment. For example, an autonomous robot that is often low on condition/health will have a high concentration of the C1 hormone within its system. The high concentration will lead to a long-term increase in the activity level ( $\Psi$ ) of the gland that secretes C1. This will mean that sub systems such as the desire to maintain a degree of personal space or find repair resources will be much more prevalent within the model. Formula 7 shows method used to facilitate the epigenetic change in activity levels ( $\Psi$ ) of the gland for hormones in the eh group.

$$\Psi_h += \frac{conc_h}{l} \quad (7)$$

where  $l$  is a constant to regulate the speed of epigenetic change.

Formula 8 shows the method in which epigenetic change can occur to the sensitivity of neurohormone receptors for the hormones in the Nh group

$$sen_h -= \frac{(strength_h - 0.05)}{j} \quad (8)$$

where  $j$  is a constant to regulate the speed of epigenetic change.

Drawing on the notion of critical periods in biological organisms, the epigenetic process above is active during the early period of the robot’s life. This critical period represents a window frame when organisms are most susceptible to the influences of external perturbations (Winks & Berthouze, 2008), mediated via hormone modulation (Crews, 2010), among other things.

## The temporal three-resource problem

The architecture described here has been tested in a temporal three-resource action selection problem framework, in which a robot needs to timely and appropriately select among and satisfy three needs using resources available in the environment in order to survive (remain operational or “alive”). Our experimental design included three different sets of experiments corresponding to three variants of an environment that pose different challenges arising from the temporal dynamics of the resources. Each set took place within a 2mx2m bordered environment inhabited by a single robot. Within each environment a number of energy and repair resources were available to allow the robot to replenish homeostatic deficits. These resources were represented by two different coloured sets of balls. The environments also contain an ambient temperature that is sensed internally by the robot.

**Scenario one** consists of the base environment with one of each resource moving in a continuous pattern at a constant speed, slightly faster than the robot’s average, around the arena, see figure 3. At the end of each movement path (represented by a letter) the resource would pause for a period of 2 seconds. In cases where the robot was in the direct path of a resource, the resource would be manoeuvred around the robot using the shortest path before returning to its original trajectory. In the case where the resource was pinned or the movement was blocked by the robot, no attempts were made to push the robot aside. Instead, movement of the resource was halted until the robot moved away and a viable path was visible. At the start of each run the resources started at a different opposite points, e.g. A and E.

Figure 3: The pathways and start points of the resources.

**Scenario two** was again based on the base environment. However, in this scenario the energy resource appears at set points within the environment once every minute, the period during which it is available reduces over time, i.e., it becomes decreasingly available. For the first five runs, the energy source would remain for 30 seconds before being removed. In the second five sets the duration was reduced to 20 seconds and the final five saw the resource only accessible for 10 seconds of every minute. The set points are the same as the start of pathways as seen in figure 3. In order to avoid biases, the order of set points where the resource would appear was

predetermined randomly before each run. The choice to have the temporal properties apply to only the energy source was done to examine the robot’s ability to deal with the increasing disparities between the availability of the repair and energy sources.

It is worth noting that the robot has no capacity to monitor time. Therefore, there is no facility to try to directly predict when the resource will appear. Rather, over time the robot will adapt to the scarcity and rarity of the resource. The use of a strict time period was to ensure each robot had same constraints and opportunities.

**Scenario three** examines the ability of the robot to adapt to the effects of dynamic climatic changes. In this experiment the standard base set up of the environment was used with one of each resource available at all times. However the ambient temperature of the environment would increase and decrease over time, simulating a day-and-night temperature cycle. The entire cycle lasts for four minutes, as can be seen in figure 4. To simplify the model, ambient temperature ranked between 0 (cold) and 10 (scorching heat).

In order to increase the dynamics of the environment, temperature was allowed to fluctuate by up 2 points to simulate potential meteorological phenomena. The fluctuations were calculated at start of each 10-second period and lasted until the next period.

Figure 4: An example of an average weather cycle with meteorological phenomena. The periods between 6 and 18 or minute 2 and 3 are analogue to daytime, with the highest temperature occurring midday equivalent to the sun at its peak in a natural environment.

## Experiments and Results

The robot was tested over a total of 35 runs split in 10/15/10 runs amongst the three previously described scenarios. Each run lasted a maximum of 10,000 steps around 10 minutes 40 seconds per run. The epigenetic system was active during the first 3 minutes (2880 steps). A second set of runs was conducted in the same manner for a robot without the epigenetic mechanism to serve as a basis for comparison. The viability of both architectures was assessed using the previously discussed *Comfort* measure and standard deviation as well as visible observation. In cases where a robot died before the end of a run, a comfort value of 0 would be recorded for any remaining loops.

### Scenario One

This environment provides the robot with two distinct challenges. The first and most obvious was the need to develop a consumption behaviour suitable for moving resources. Secondly, this environment presents the first situation where the robot can be damaged by other elements (objects or organisms) of the environment. While as previously stated resources will move around the robot if it is directly in their path, they will still move close enough to encroach upon the extended body, causing damage. Therefore, the robot will also need to adapt to co-exist with the resources, not just how to exploit them. The results of the first experiments can be seen below in figure 5.

Figure 5: The combined results for Scenario One.

As can be seen in figure 5, the epigenetic robot performed at a higher level overall, but more interestingly had a much lower standard deviation of 0.05 compared to 0.17. The differences in standard deviation can be attributed to the dynamic nature of the resources. In some situations the robot was positioned in the ideal location to catch and consume resources as they passed. This led to timely management of the robot's homeostatic needs. However, in other cases the robot would need to actively move across the arena and chase a resource. Since the resources moved slightly faster than the robot's average speed, the motivation to consume the resource had to outweigh the motivation to limit speed in order maintain a low temperature.

Distinctive behaviour developed for each of the architectures in this environment. The epigenetic model would develop an "ambush-like strategy": the robot would remain sedentary until an energy source passed closely, at which point the robot would give chase at full speed often pinning the resource to a wall until it had finished consuming it.

In contrast, the non-epigenetic model would engage in "drawn-out chases". As the motivation to consume the resource allowed it to generate the speed needed to catch up, excess heat was generated. This heat generation led to premature end of the chase on a number of occasions. Finally the epigenetic robots displayed more adaptive behaviour at avoiding unnecessary collisions with resources, and almost no unwanted collisions occurred after the early periods.

### Scenario Two

In scenario two, we tested the ability of the robot to deal with resources only available for limited periods of time. The 15

runs were divided into 3 groups of increasingly challenging runs with the resource present for 30/20/10 seconds of every minute, challenging the robot to act in a timely manner when the opportunity to recover from homeostatic deficits was present. This temporal quality only applied to the energy resource. This further challenged the robot to overcome the "distraction" of the more readily available repair resource. The results of this scenario can be seen below in figure 6.

Figure 6: The combined results for Scenario Two.

Both robots performed at a similar level during the first five runs with 30 second window of opportunity. While the epigenetic robot moved more promptly to resources when they appeared, neither robot ever was in any real danger. However, as the window of opportunity shrunk, the differences between the two models became very apparent, as can be seen in figure 6.

As the point where the resource would appear next was unknown to the robot, it was inevitable that both architectures would miss some opportunities to replenish. However, the epigenetic model was generally quicker to find any resource due to the development of the E1 and D1 glands, thus giving the robot a greater chance of survival also when the opportunities were missed.

Finally, due to missed opportunities to fully recover deficits, both robots often contained significant level of the D1 hormone. This in turn resulted in higher occurrences of collision in later runs, subsequently increasing the need for repair resources. In multiple cases this led to similar levels of need for both the energy and repair resource. This resulted in the non-epigenetic robot sometimes going to the readily available repair source during the limited periods when the energy source was present and seen. This occurred on some occasions even when condition deficits were not significant. In contrast, the epigenetic model had adapted to the rarity of the resource. It only missed the opportunity to replenish energy once. This occurred when its condition levels were critical. In total, 7 of the non-epigenetic robot runs ended prematurely compared to a single death in the epigenetic model. Due to the high level of fatalities, the hormone-only model actually had a lower standard deviation of 0.03 in contrast to 0.08 in the epigenetic model.

### Scenario three

In the final scenario we tested the ability of the two robot architectures to deal with cyclical climates, with the cycle of change in ambient temperature previously shown in figure 4. Like scenario two, this environment challenged the robot's

ability to take advantage of limited windows of opportunity. During the periods where ambient temperature reached its peak, even limited movement soon led to overheating. Two of each of the resources, spread evenly in each corner, were constantly available in the environment. The results for this experiment can be seen in figure 7.

Figure 7: The combined results for Scenario Three.

As can be seen, the epigenetic robot had much greater success. After the initial 3 or 4 cycles the robot's hormone glands had developed in such a way that, during periods with the highest ambient temperature, virtually all actions would be suspended. As soon as the ambient temperature dropped, the robot would move to replenish any deficits. The epigenetic robots developed two contrasting behaviours in order to survive the periods of high ambient temperature. One group simply over consumed and in effect "hibernated". The second group would instead stay near the energy source at all times apart from the occasional need to repair, allowing itself to consumer energy during the increased climate with only very limited movement needed.

In contrast, the non-epigenetic model often ran low on energy during the day cycle. This resulted in the robot being forced to move to energy sources, generating significant overheating, which led to the death of the robot on 3 occasions.

## Conclusion

In our past study (Lones and Cañamero 2013) we have shown how epigenetic changes through hormone modulation increase the adaptability of a robot. Specifically we demonstrated how this process leads to behaviours tailored to specific environmental niche. These robots were placed into different environments with exactly the same starting architecture. However, through epigenetic processes, the robots developed distinct traits and behaviours depending on the environment in which they developed.

In the study presented in this paper, we have investigated the same architecture under new criteria. Specifically, we focused on the ability of the robot to adapt to environments that presented temporal dynamics challenges. In the first experiment, the robot needed to adapt to fast-moving resources. While the robot could simply have "chased after" the resource at top speed, this would lead to unwanted overheating and would not guarantee appropriate satisfaction of its homeostatic needs. Instead, the robot developed what could be considered equivalent to an "ambush-like hunting

tactic". In the second experiment, the robot was challenged to adapt to limited windows of opportunity to satisfy a homeostatic need, all the while needing to adapt and disregard opportunities offered by more easily available resources that permitted to satisfy other needs. Needing to find a balance between maintaining the different homeostatic needs, the robot was able to respond in a timely manner to rare occurrences while still finding time to satisfy the other needs. In the final experiment, we examined the ability of the robot to adapt to cyclical events. Under this scenario, the robot needed to fully utilise the cooler periods of the day, which allowed it to be in a position to survive hotter periods when most actions would need to be suspended. This experiment marked the first time we saw the epigenetic model divide into two distinct groups. Each group developed a different method to deal with the debilitating temperature.

As we have shown, epigenetic adaption though hormone modulation potentially offers a suitable method to allow a base architecture to develop behaviours to adapt to environments presenting different temporal challenges.

# Hidden information transfer in an autonomous swinging robot

James Thorniley<sup>1</sup> and Phil Husbands<sup>1</sup>

## Abstract

This paper describes a hitherto overlooked aspect of the information dynamics of embodied agents, which can be thought of as hidden information transfer. This phenomenon is demonstrated in a minimal model of an autonomous agent. While it is well known that information transfer is generally low between closely synchronised systems, here we show how it is possible that such close synchronisation may serve to “carry” signals between physically separated endpoints. This creates seemingly paradoxical situations where transmitted information is not visible at some intermediate point in a network, yet can be seen later after further processing. We discuss how this relates to existing theories relating information transfer to agent behaviour, and the possible explanation by analogy to communication systems.

## Introduction

The dynamics of embodied agent-environment systems are increasingly analysed using information theory (Lungarella and Sporns, 2006; Pfeifer et al., 2007b; Bertschinger et al., 2008; Klyubin et al., 2008; Pitti et al., 2009; Williams and Beer, 2010; Moiola et al., 2012; Schmidt et al., 2012). This paper adopts this approach and demonstrates a phenomenon that is consistent with the analogy to communications, but thus far seemingly overlooked in studies of information transfer in embodied agents. We describe “hidden” information transfer in a simulated robot: strongly physically coupled parts of the system carry information between separated endpoints, without such information transfer being visible between the carrier components themselves.

Information transfer is often characterised using forms of *transfer entropy* (Schreiber, 2000), itself a nonlinear generalisation of Granger causality (Barnett, 2009). Information transfer from  $X$  to  $Y$  is quantified by the relative improvement in statistical prediction of the future states of  $Y$  when the current state of  $X$  is known in addition to the already-known historical states of the target variable  $Y$ . A known issue, and potential source of confusion, is that information transfer is not a measure of the *physical strength* of coupling – a common example being synchronised systems, where very high coupling may mean that two time series are almost

identical, leading to little prediction improvement and hence low transfer entropy in spite of strong physical coupling (this is seen in e.g. Thorniley, 2011). This is sometimes regarded as a failure of transfer entropy to properly capture *causal* influences (Ay and Polani, 2008; Lizier and Prokopenko, 2010; Janzing and Balduzzi, 2012). The agent model used in this paper will exhibit this type of phenomenon, but in addition we will show that although strongly coupled components may exhibit low transfer entropy, they may still act as information conduits, hiding information transfer between more separate components.

Our model is a reactive robot designed to behave like a child swinging on a swing. As the feedback gain in the robot’s controller increases, a self sustaining oscillation is created. The agent has a simple neural model acting as its brain, which is connected to the environment via its body. The state of the agent’s neural system cannot (physically) influence the environment apart from by first affecting its body. However, we demonstrate that information transfer can take place from brain to environment *without* information transfer from brain to body. This shows how information transfer can be hidden within the agent, and revealed by its interaction with the environment.

This is the key result of this paper – information can pass through a chain of coupled systems, e.g.  $A$  to  $B$  to  $C$  such that there is a high information transfer from  $A$  to  $C$  but *not* from  $A$  to  $B$ , even though physically there is no alternative route. In the discussion at the end of the paper we will consider how similar effects occur in communication systems by way of analogy to our agent based model.

This paper is organised as follows: the next section below describes the model swinging agent and its general dynamical features. The analysis in the following section shows the information hiding phenomenon by analysing the information transfer between each component of the system. The final section discusses this result and considers the implications for the study of embodied autonomous agents in terms of information theory.

Table 1: Variables and parameters

Symbol	Type/Value	Description
$\theta$	Variable	Angle of pendulum from downward vertical
$\omega$	Variable	Angular velocity of pendulum ( $d\theta/dt$ )
$r$	Variable	Current pendulum extension
$v$	Variable	Rate of pendulum extension ( $dr/dt$ )
$u$	Variable	Force control variable – force on bob due to effector
$F_a$	Intermediate	Force on bob due to acceleration
$F_s$	Intermediate	Force on bob due to spring
$A$	Independent variable (0-80)	Motor neuron output at saturation
$g$	9.81	Acceleration due to gravity
$b$	0.3	Pendulum damping coefficient
$\rho$	2	Motor neuron sensitivity
$\phi$	20	Control parameter
$k$	100	Spring force constant
$c$	20	Spring damping ( $= 2\sqrt{k}$ for critical damping)

### Reactive swinging agent

The system studied here is a simplified model of a child swinging on a swing. The swing itself will be modelled as a rigid massless rod attached to a fixed pivot at one end with a mass (being the mass of the agent) at the other end. The agent’s motor control consists in its ability to move the mass up and down (towards and away from the pivot). There are two general ways to approach the dynamical modelling of such a system. It is possible to use a “kicked pendulum” approach where a periodic forcing function is used to perturb the mass (e.g. Belyakov et al., 2009). However it has been found that even though a pendulum can be made to swing this way, the limit cycle produced is in fact unstable, and thus this is in a practical sense impossible to achieve in the real world, suggesting that a better approach is the “self-excited” oscillator (Pinsky and Zevin, 1999; Zevin and Filonenko, 2007). Here the agent creates a positive feedback loop by adjusting the distance from the mass to the pivot point (e.g. by raising and lowering the centre of mass of the agent relative to a fixed attachment point at the end of the rod). This create a stable limit cycle as well as a resting point (where the swing is pointing straight downwards and there are no vibrations to amplify). Thus if the swing is given an initial “push”, the movement of the agent will sustain the oscillation, hence the system is described as self-excited. This approach treats the agent as a reactive system in the sense of Brooks (1986). This section provides further details on the implementation of this system.

A representation of the model is shown in figure 1. There is a massless rod with length normalised to one arbitrary unit. It makes an angle  $\theta$  with the vertical axis along which the gravitational force  $g$  applies. The “agent” consists of a mass-spring-damper system attached to the end of the rod. The mass is influenced by the gravitational force, along with

Figure 1: Spring based model of the swinging agent

the centrifugal effect of rotation and the forces created by the spring: linear contraction  $kr$  where  $k$  is a constant and  $r$  is the extension of the spring, and damping  $cv$  with  $c$  another constant and  $v = \dot{r}$  – the linear velocity of the mass in the direction of the spring. The agent creates an effector force  $u$  which acts on the mass, but this is derated according to the current absolute extension of the spring, modelling a linear motor which produces less force output when it is already extended.

The full system can be described by the following equations. Table 1 lists each of the variables and parameters used. Dots represent differentiation with respect to a non-dimensionalised time variable  $t^1$ :

<sup>1</sup>For simplicity all variables are treated as dimensionless, though the choice of  $g = 9.81$  suggests the system could be treated as a one metre long pendulum with the agent mass at one kilogram, and time in seconds.

$$\dot{\theta} = \omega \quad (1)$$

$$\dot{\omega} = -\frac{g}{1+r} \sin(\theta) - b\omega \quad (2)$$

$$\dot{r} = v \quad (3)$$

$$\dot{v} = \frac{u}{1+|r|} + F_a + F_s \quad (4)$$

$$\dot{u} = \phi(A \tanh(\rho v) - u) \quad (5)$$

The last equation describes the internal dynamics of the agent's reactive controller. The agent senses the current velocity  $v$  of its spring, and passes this through a simple sigmoidal neuron, which determines a desired output force  $A \tanh(\rho v)$  where  $A$  and  $\rho$  are parameters. The actual output force  $u$  moves towards this desired value in proportion to its current error according to the rate parameter  $\phi$ .

The acceleration of the mass in the direction of the pendulum rod  $\dot{v}$  is given by the resultant force (we assume the mass is normalised to one arbitrary unit). That is, equation 4 shows  $\dot{v}$  is the sum of the force due to acceleration  $F_a$  (i.e. gravity and centrifugal forces, equation 6) and the force due to the spring  $F_s$  (equation 7) along with the effector force described above.

$$F_a = g \cos(\theta) + (1+r)\omega^2 \quad (6)$$

$$F_s = -kr - cv \quad (7)$$

We can treat the different dynamical variables as components of either the agent or environment, and further subdivide the agent into "brain" and "body" as shown in figure 2. The intention is to treat the agent as dynamical system which is "embodied" in the sense that its overall behaviour is a result of the close coupling of the agent's body, brain and environment (Pfeifer et al., 2007a). The main sensor variable is  $v$  – the input to the neuron, though the spring extension  $r$  can also be conceptualised as a component of the agent's sensory system. The motor output is represented by  $u$ , and the environment consists of the pendulum system:  $\omega$  and  $\theta$ .

The fixed parameter values used in the following simulations are shown in table 1. The parameter  $A$  effectively controls the feedback gain and will be varied as the independent variable in what follows.

The bifurcation plot in figure 3 gives an indication of the general dynamical features of the system. These plots are obtained by recording the angular speeds at which the swing passes through the downward direction, having been initialised with a random angular velocity and the "transient" time while the system is still far from a stable cycle or point discarded. Data is obtained using Runge-Kutta integration – all results in this paper are based on an integration step size of 1/50th of a time unit, with a simulation length of 1000 time units. With  $A$  low, less than about 10, there is a

Figure 2: The agent and environment in terms of dynamical variables

single, globally stable fixed point – i.e. there is insufficient feedback for the agent to actually swing. Between feedback gains of around 10 and around 50, the agent usually swings side to side (represented in blue in the figure) – where the agent returns to  $\theta = 0$  swinging in a different direction each time. Above  $A = 30$  another stable cycle appears where the pendulum swings over the top rather than side-to-side, i.e. it returns to  $\theta = 0$  travelling in the same direction (same sign of  $\omega$ ) each time. Note that the two cycles coexist between values of  $A$  around 30 to 50, but above that only the rotating motion occurs. Finally, above  $A = 70$ , a transition to chaotic motion occurs – above this point the system will sometimes rotate and sometimes swing side to side during a single trajectory. The fixed point where the system does not swing is locally stable for values of  $A$  less than around 33, meaning that sometimes the system will tend towards resting rather than either of the limit cycles. Thus the ultimate behaviour of the system is in general dependent on the initial conditions as well as the particular value of  $A$  chosen.

We now consider a slight alteration to the model. In practice, no sensor is perfect, and thus the input to the neuron might conceivably be modelled as a stochastic variable with a slight perturbation  $\varepsilon_v$ , so equation 5 becomes:

$$\dot{u} = \phi(A \tanh(\rho(v + \varepsilon_v)) - u)$$

Assuming  $\varepsilon_v$  is small we can linearise its effect model it as a random additive perturbation on  $\dot{u}$ :

$$\dot{u} = \phi(A \tanh(\rho v) - u) + \phi A \rho \text{sech}^2(\rho v) \varepsilon_v$$

In order to practically simulate the system, it must be written as stochastic differential equations. Specifically, we convert the equation for  $u$  (which is the only variable where we directly add noise) into *Langevin equation* form:

$$du = \phi(A \tanh(\rho v) - u)dt + \phi A \rho \text{sech}^2(\rho v) \sigma dW$$

Where  $W$  represents a Wiener process, and a new parameter  $\sigma$  is introduced to control the strength of the random

Figure 3: Bifurcation plot showing the behaviour of the system as the internal gain  $A$  is increased. Simulations are performed at each of 300 linearly spaced points between  $A = 0$  and  $A = 80$ . Plot shows absolute angular velocity of the pendulum recorded as it passes through the “downward” ( $\theta = 0$ ) plane of its state space – points in blue are returns to  $\theta = 0$  where the sign of  $\omega$  changed in between returns (i.e. the agent is swinging side to side) and points in red show returns in the same direction (the pendulum has swung over the top). The grey area shows the numerically estimated stability region for the fixed point where  $\omega = 0$  – i.e. if the system is within this region it will eventually stop swinging. Outside of this region, it will go to either a swinging or rotating stable cycle.

Figure 4: Bifurcations with noise  $\sigma = 0.25$

noise. This equation can be numerically solved using the stochastic strong order 1.0 Runge-Kutta algorithm. The full details of this approach including integration algorithm are found in Sauer (2012). The overall effect is that  $u$  behaves as if the neuron senses the current velocity  $v$  with additive Gaussian white noise, where the noise power is increased by increasing the newly introduced parameter  $\sigma$ . Figures 4 and 5 show the effect of increasing  $\sigma$  on the bifurcation structure – the main features remain much the same, but the crossing points are now somewhat random.

As well as making the model more “realistic”, introducing this random perturbation ensures that the system is generally ergodic, which facilitates the correct calculation of transfer entropy. Without this property, the probabilities estimated from time series data tend to make little sense (see Breiman,

Figure 5: Bifurcations with noise  $\sigma = 0.5$ . Note that since the system is stochastic, the stability regions are not deterministically defined (close to the edge of the region shown, some trajectories may tend towards the fixed point and some towards the limit cycle depending on chance). The region shown shaded corresponds to the median stable boundary found in 20 simulation runs at each value of  $A$ .

1969, for a discussion). This slight randomness also means that even for very closely synchronised variables there will likely be at least some transfer entropy measured, as there will be a constant introduction of entropy inside the system.

### Information transfer analysis

Transfer entropy is generally defined for two time series  $X$  and  $Y$  as a relative entropy or conditional mutual information:

$$TE_{X \rightarrow Y} = \sum P(x_t, y_{t+\delta}, y_t) \log \frac{P(y_{t+\delta}|x_t, y_t)}{P(y_{t+\delta}|y_t)}$$

The data points being taken at discrete time intervals  $\delta$ , e.g.  $X = (x_{t0}, x_{t0+\delta} \dots x_{t0+n\delta})$ . The sum is taken over the support of  $P(x_t, y_{t+\delta}, y_t)$  – i.e. all possible combinations of values for the three variables. In this analysis we use the time interval  $\delta = 1$  (i.e. 50 integration steps, corresponding to approximately one quarter of a cycle).

It is problematic to calculate the transfer entropy on continuous-valued time series such as we have here. We have used symbolic transfer entropy (Staniek and Lehnertz, 2008), which uses a convenient rank transform to find an estimate of the transfer entropy on continuous data without the need for kernel density estimation.<sup>2</sup> First an embedding dimension  $m$  is chosen (we use 4), for each  $n \geq m$  we set  $\hat{x}_{t0+n\delta} = \text{rank}[(x_{t0+(n-m+1)\delta} \dots x_{t0+n\delta})]$ , where rank converts a sequence into its sort order, e.g. (0.0, 0.4, 0.3, 0.25) becomes (1, 4, 3, 2). That is, each original observation (after embedding in  $m$  dimensions) is a continuous vector ( $x_t \in \mathbb{R}^m$ ) and after transformation each observation is assigned one of the  $m!$  possible permutations

<sup>2</sup>Alternatives exist such as  $k$  nearest-neighbour methods (Kraskov et al., 2004; Evans, 2008). At this time we are not aware of a reason to prefer one method over the other in this instance.

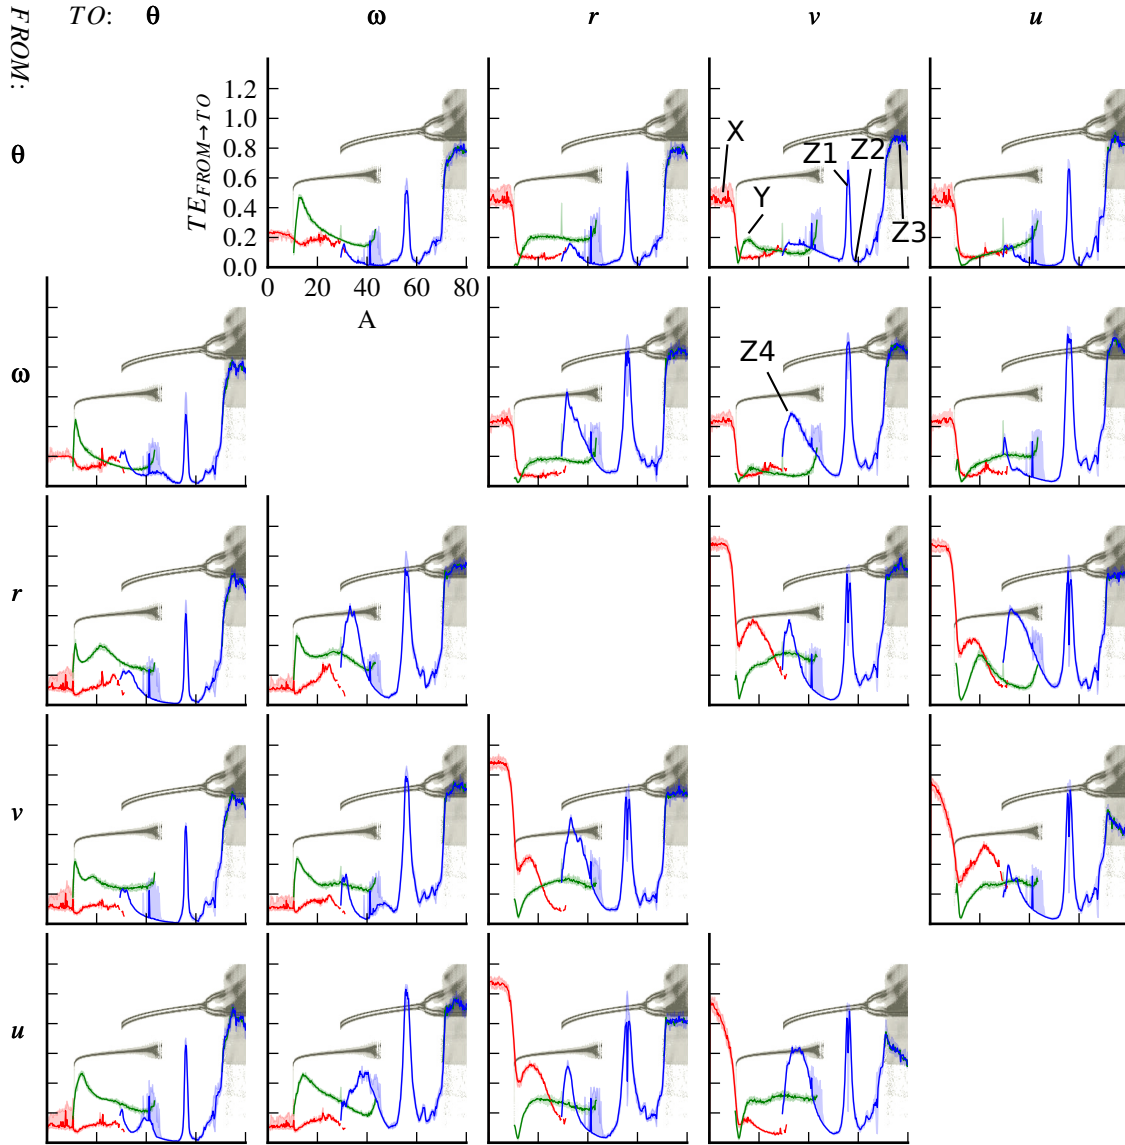

Figure 6: Symbolic transfer entropy in bits from each dynamical variable to each other one as the internal gain  $A$  is varied in the system with noise  $\sigma = 0.25$ . Note that figure 7 shows some of the same data in a form that is easier to interpret for the effects we are primarily interested in – the current figure is provided to show the context for the particular values of  $A$  chosen for re-plotting in figure 7. The background of each plot shows in grey a copy of the bifurcation diagram from Figure 4 – this is intended to help identify the correspondence between recorded transfer entropy and system behaviour. The results from 20 runs are shown after grouping by behaviour mode (color online): red for stable (non-swinging), green for side-to-side swinging and blue for rotational motion. For each behaviour the median is calculated for plotting and the shaded area around each line shows the 10th-90th percentile range where it is visible (for most values of  $A$  there was very little variation in the results). For comparison, the bifurcation plot for the system is shown in grey in the background. Some key points on the graphs are labelled in the  $\theta \rightarrow v$  and  $\omega \rightarrow v$  plots (the same features are present on some of the other plots as can be seen): at X the transfer entropy for low feedback gains (stable behaviour) is often high; at Y there is a peak in the curve for side-to-side swinging behaviour at around  $A = 12$ ; Z1 is a notable peak in the rotational swinging behaviour, which appears to correspond to some complexity in the behaviour not captured by the bifurcation diagram, Z2 is a trough at around  $A = 50$ ; Z3 and Z4 show peaks in transfer entropy which can easily be related to features of the bifurcation diagram which indicate higher complexity – the chaotic behaviour at very high gains and the behaviour close to the bifurcation point.

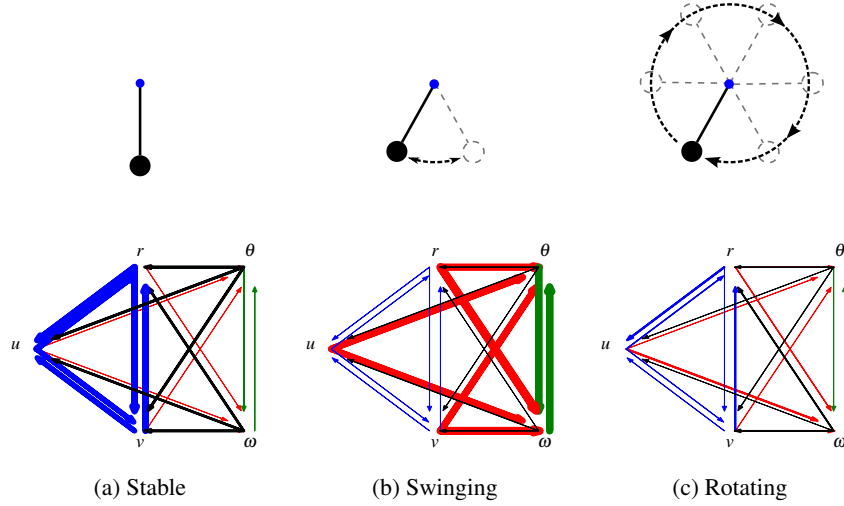

Figure 7: Median transfer entropy under three different behavioural regimes represented by arrow widths. Arrows are colored blue for information transfer within the agent (variables  $u$ ,  $r$  and  $v$ ), green for within the environment (variables  $\theta$  and  $\omega$ ), red for agent to environment and black for environment to agent. See Figure 2 for classification of variables. (a) Low feedback gain ( $A = 2.6$ ), the system cannot maintain a periodic motion and tends towards the stable state. Higher transfer entropy is seen within the agent. (b) Moderate gain ( $A = 12$ ), the agent will swing side to side. This graph illustrates the information hiding effect (see text). (c) High feedback ( $A = 50$ ), the system rotates over the top. At this value almost no transfer entropy is seen in any direction. Note that the arrow widths in (a) are 1/3rd the scale of the widths in (b) and (c) since the transfer entropy values are generally much larger in (a).

of a sequence of length  $m$ . The permutation is denoted  $\hat{x}_t$  and for ease of calculation could obviously be assigned an integer representation according to an arbitrary one-to-one mapping. The formula for symbolic transfer entropy is then

$$STE_{X \rightarrow Y} = \sum P(\hat{x}_t, \hat{y}_{t+\delta}, \hat{y}_t) \log \frac{P(\hat{y}_{t+\delta} | \hat{x}_t, \hat{y}_t)}{P(\hat{y}_{t+\delta} | \hat{y}_t)}$$

With the probabilities estimated in the natural manner for discrete variables according to frequency of occurrence, i.e.  $P(\hat{x}_t = X)$  would simply be the number of time points where  $\hat{x}_t$  is found to be  $X$  divided by the total number of observations taken.

On every experimental run, the system is initiated with all dynamical variables set to zero except for  $\omega$  which is taken uniformly at random from  $[-10, 10]$ . The first 100 time units are treated as transient non-stationary data and discarded, and the remaining 900 data points are fed to the symbolic transfer entropy calculation. This process is repeated ten times with different initial conditions, and the trajectories recorded are classified according to their final behaviour mode: resting, swinging or rotating.

The set of results in figure 6 shows all the transfer entropy values calculated for the system using a noise amplitude of  $\sigma = 0.25$ , taking each possible combination of source and target variables. This shows a few basic features of the results. We see as expected that the transfer entropy does not

straightforwardly correspond to physical coupling – there is no simple correspondence between the independent variable  $A$  and the transfer entropy value. We also see that very different patterns of information transfer are observed for the different behavioural regimes, even at the same value of  $A$ .

A simpler graphical representation of the transfer entropy is shown in figure 7. This shows the median transfer entropy for a particular behaviour at a chosen value of  $A$  as the width of an arrow pointing in the direction of information transfer. The arrows have been colour coded by the way in which they connect the brain, body and environment components.

The most striking result for our purposes is shown in figure 7b, where the feedback gain is moderate, resulting in a natural swinging behaviour. Here, the highest information transfer is along the paths coloured red which emanate from the agent (according to the classification in Figure 2) and flow towards the environment. This includes the arrows which directly connect the output of the motor neuron  $u$  to the environment variables  $\theta$  and  $\omega$ . However, there is no direct physical connection along this path since the coupling between the brain and environment is always mediated by the body. This is shown in equations 1 to 5 – the neuron output  $u$  does not appear on the right hand side of the equations for  $\dot{\theta}$  and  $\dot{\omega}$ , and hence it can only influence these variables through the intermediate coupling to its body (since the body displacement  $r$  *does* influence  $\omega$ ). Thus the informa-

tion transferred from  $u$  to  $\omega$  (shown by a thick red arrow) for example is surely carried across the chain  $u \rightarrow v \rightarrow r \rightarrow \omega$ , yet there is *low* information transfer from  $u$  to  $v$  and  $r$  (illustrated by the thin blue arrows). It is in this sense that we claim this shows a form of hidden information transfer – we know that the brain can only influence the environment by going through the body, but even when a high information transfer is measured from brain to environment, there is a smaller amount from brain to body

Figures 7a and 7c do not clearly show this phenomenon, since it is in no sense necessary for it to be present. Figure 7a seems to show the strongest connections within the agent when the feedback gain is low and the system is resting, which can be explained by the fact that the source of entropy here is the sensor noise inside the agent, and since the agent is not swinging it may move up and down, but is not likely to influence the angle of the pendulum. In figure 7 the very high feedback coupling is likely creating a highly synchronised dynamic where the observed transfer entropy is very low.

## Discussion

The key result of this work is shown in figure 7b, where during the entrained oscillatory motion of the system, the transfer entropy is shown to be higher from the brain to the environment than it is from the brain to the body, even though it is not possible for the brain to influence the environment without that influence passing through the body.

It appears that the entrained behaviour leads to a reduction in the transfer entropy measured within the agent, as can be seen by comparing the blue arrows between figures 7a and 7b. This is likely due to the close synchrony between these variables when the agent is swinging – a factor that is known to generally reduce measured transfer entropy. What is interesting is that though the swinging behaviour appears to decrease the transfer entropy within the agent, it also corresponds to increased information transfer from the agent to its environment. This is a clear demonstration of the importance of the agent’s embodiment to the information dynamics of the system – the interesting (as in measurable) interaction takes place between the agent and the environment rather than within the agent.

What we are calling *information hiding* is the way in which information coming from a variable we specifically associate with the agent’s neural system, i.e.  $u$ , appears to pass straight to the environment without having to “go through” the body, in spite of the fact that we already know that, in a physical sense, it must, since only the agent’s body is physically coupled to the environment.

It is worth attempting to gain a little intuition for how this effect is working. For an analogy that is perhaps useful in the current context, consider the simplest type of encryption system based on a symmetric key illustrated in figure 8. A key is a randomly chosen binary sequence that

Figure 8: A simple encryption system

has been previously shared between a sending and receiving party. The sender can encrypt a message by performing the *XOR* operation bit-wise between the key and the message. However, since the key was chosen randomly, the resulting encrypted signal should be statistically independent of the transmitted message – the encryption operation appears (to anyone without the key) to flip bits of the message at random (i.e. it randomly changes some 1’s to 0’s and some 0’s to 1’s). However, with the key, it is trivial to reconstruct the original message – the same *XOR* operation is simply applied using the previously shared key. Symbolically, if we have a transmitted message  $T$ , encrypted signal  $S$  and received signal  $R$  then we have a very low  $I(T; S)$  yet high  $I(T; R)$ . Though expressed in terms of mutual information rather than transfer entropy, this is essentially the same information hiding phenomenon as we have been discussing. Indeed if we assume the individual bits of the message and the key are independent of each other then  $TE_{T \rightarrow S} = I(T; S | \text{history}(S)) = I(T; S)$  and so on.

The information hiding process can thus be seen as a message being obscured by at some point and later reconstructed. In the example above this function is performed by the encryption system and is dependent on having a piece of secondary data (the key) shared between the two endpoints via some alternative channel to the main signal path. Of course, the encryption system is carefully designed to achieve this – it requires the deliberate sharing of the key. However, comparable processes have been found relying only on chaotic synchronisation: Cuomo and Oppenheim (1993) demonstrated that synchrony between a pair of coupled Lorenz attractor systems can be used to “hide” information in a similar way.<sup>3</sup> Their experiment suggests that it is plausible that information could be hidden by a dynamical process such as the one studied here without the need for the deliberate design of an encryption system.

This phenomenon should not be viewed as information being completely lost to the world and then coming back

<sup>3</sup>Note that this system is not generally regarded as computationally secure as an encryption mechanism since the reconstruction circuit (which effectively serves as the “key”) can be relatively easily inferred using attractor reconstruction on the transmitted signal.

– rather it is simply hidden and then reconstructed by the action of some dynamical system. We have interpreted information here as a statistical summary of collected data – not as a physical quantity that exists in the world.

We have said little explicitly about causation, though of course to say that the brain must influence the environment via the body suggests a causal interpretation. Recent work has studied the relationship between transfer entropy and causal inference in part motivated by phenomena similar to the one described here (e.g. Ay and Polani, 2008; Lizier and Prokopenko, 2010). Information theory has also been applied successfully in the context of embodied systems (e.g. Ay et al., 2008; Klyubin et al., 2008). Both of these connections are relevant: can information hiding as presented here be useful in any sense as a guide to causal inference? How should the current case study be connected to wider theories of embodied behaviour? We aim to address these questions in future work.

The recent surge of the “Maker” movement (Anderson 2012) is largely driven by the increasing availability of the personal fabrication technology such as 3D printing (Lipson & Kurman 2013). Widespread diffusion and adoption of personal fabricators based on von Neumann style general purpose constructors are considered as one of the central possibilities of living technology (Bedau et al., 2010; Rasmussen et al. 2011). This is expected to cause a major shift of design and manufacturing power from large firms to individuals, in ways similar to how personal computers and information technology changed information production and dissemination in our society over the last few decades.

Personal fabricators occupy an interesting position in the network of goods and products from an artificial chemistry perspective (Dittrich, Ziegler & Banzhaf 2001). The whole manufacturing system in human civilization can be understood as a huge metabolic network in which reactants and catalysts are goods (raw materials and products) and fabricators (production tools ranging from human hands, hammers and knives to advanced computers and large-scale factories), respectively (Becker et al. 2013). In this context, the role of personal fabricators is close to that of general-purpose catalysts, such as ribosomes in biological systems. Such general-purpose catalysts tend to have high complexity and slow reaction rates, yet they can produce a great variety of complex products.

The emergence of ribosomes and gene-protein translation mechanisms in the history of life enhanced diversity, functionality and complexity of biomolecular machines significantly, clearly marking one of the major evolutionary transitions (Maynard-Smith & Szathmari 1997). This observation naturally leads one to ask the following question:

*What kind of societal transition may occur due to the rise of personal fabricators?*

This is not a trivial question to answer because of the differences between biological and socio-economical systems. Unlike biological cells, modern socio-economical systems are largely driven by individuals who have conflicting personal and financial interests and strategically determined behaviors imbedded in a market driven economical system. Such behavioral complexities of anthropomimetic agents are often omitted in computational social simulations, though they would be necessary in order to capture relevant socio-economical dynamics.

To investigate the potential societal impact of the rapidly emerging personal fabrication technology, we developed an agent-based simulation of designing-manufacturing-economy dynamics. In this model, agents design and produce goods using other goods as materials based on their knowledge of manufacturing processes, and then trade the products with other agents, in order to maximize their own utility (largely determined by monetary profit). The system consists of two main components: (i) *the static universal product network* made of all  $n$  possible goods using  $m$  materials in different ways determined by their connections and (ii) *the dynamic economy* made of agents and their realized markets, which are where goods are actually traded.

*The static universal product network* represents the global set of all manufacturing processes possible (including not yet realized) in the simulated world. It is randomly generated using a heuristically designed algorithm as a bipartite network made of two types of nodes: reactants (raw materials and products) and reactions (production processes). Each reaction combines multiple reactants and produces another reactant at a certain rate. In this network, fabricators can be identified as catalytic reactants that do not increase or decrease in number through a reaction process.

Each catalytic reactant (fabricator) has its inherent complexity and utility values assigned to it. The complexity of a product is always bounded by the complexity of the fabricators and products used in its production process. Fabricators with high complexity, slow reaction rates but great universality (i.e., ability to catalyze a great number of reactions) represent general purpose personal fabricators. In contrast, fabricators with medium complexity, fast reaction rates and high specificity represent large-scale mass-production factories. Fabricators with low complexity, slow reaction rates and high universality represent primitive manufacturing tools such as hand tools. Agents are initially equipped with the fabricator with lowest complexity to start with.

*The dynamic economy* consists of agents and their markets. Each agent has the following properties: (1) amount of money it has, (2) inventory and price of goods they own (including fabricators), (3) utility associated with each product in the product network, and (4) the combined utility of all of the products in their inventory. At each time step, an agent randomly generates a finite number of possible actions (which goods to produce, which goods to purchase, etc.) and assesses

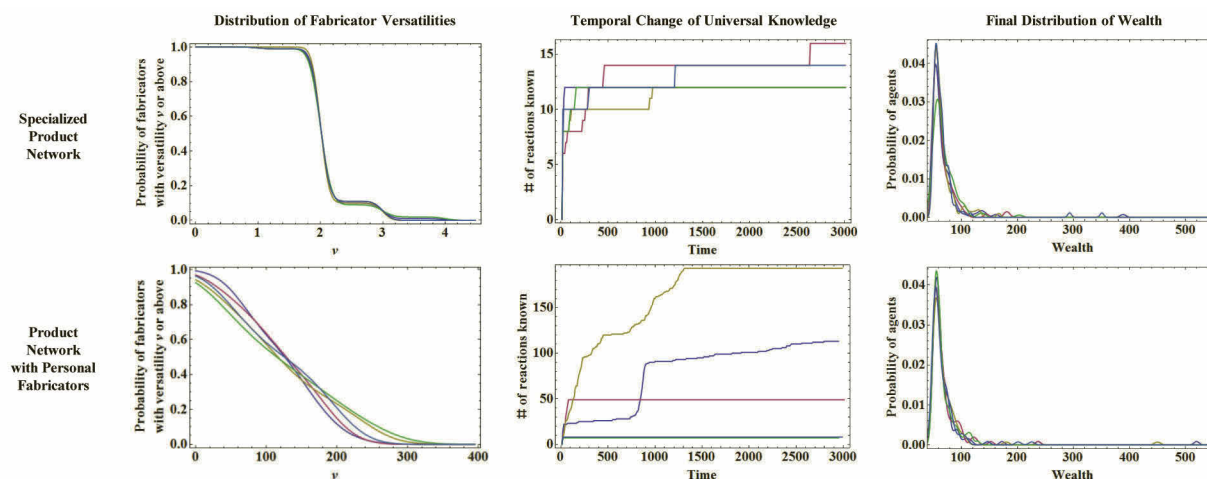

Figure 1: Simulation results. Results of five independent runs are shown in each plot. Left column: Complementary cumulative distributions of fabricators' versatilities. Top (across all columns): Results with a specialized product network without versatile personal fabricators. Bottom (across all columns): Results with a production network with versatile personal fabricators.

them to choose one that will increase its overall utility most as the next action.

Agents have partial knowledge about the universal product network (i.e., subgraph of the network), which is shared amongst all agents. At any given time step, there is a small probability by which an agent discovers (and implements) a new reaction in the universal product network and add this information to the communal knowledge base. This simulates gradual accumulation of innovations in society over time. An agent is only able to produce products that are included in the communal knowledge base.

Using the agent model described above, we conduct simulations with the abundance of personal fabricators in the universal product network varied as the experimental input. More specifically, we test two different scenarios of the universal product network: (1) a specialized product network where the fabricators' versatilities (i.e., number of products a fabricator can produce) are quite low and homogeneous (Fig.1, top left), and (2) a product network where the fabricators' versatilities show a fat-tail distribution in which some fabricators can produce a great number of different products (representing the possibility of personal fabricators; Fig. 1, bottom left).

Our preliminary simulation results show an interesting difference in technological development between the two scenarios, as shown in Fig. 1 (middle and right). With the specialized product network, after 3,000 time steps, agents tend to discover only a small number of reactions (top middle). In contrast, with the product network with versatile personal fabricators, agents can discover an order of magnitude larger number of reactions (bottom middle), and they often achieve innovative breakthroughs (seen as rapid increases of curves). The final distributions of wealth are found to be similar in both conditions, however (bottom right).

We note that our simulation is still preliminary and limited in several aspects. First, to include the key components the complexity of the current simulation is quite high as it implements a number of assumptions involved in designing-manufacturing-economy dynamics. This makes it rather difficult to explore, calibrate and validate experimental settings.

Second, the economic rules currently used to determine the prices of goods are simplistic and could be improved by implementing more well-established economics theories. Third, the incentives for agents to discover and produce new innovative products are currently given by inherent utility assigned to each potential product, which may not be a valid assumption to make. We are currently working on a simplification, revision and more thorough validation of our simulation.

**Acknowledgements:** This work was partly conducted as a senior design project of the Department of Bioengineering at Binghamton University. We thank Dr. George Catalano, Professor of Bioengineering and instructor of the senior design course sequence, for his generous support and guidance over the past year. We also thank Dr. Andreas Pape for his advice on the modeling of agents' economic decision making.

## Abstract

This paper describes and investigates a swarm intelligence system with similarity-oriented behavioral rules, hierarchical clustering and evolution by random mutation. The evolutionary scheme is based on the Bak-Sneppen model of co-evolution between interacting species. The swarm of species, in this case, is randomly distributed on a 2-dimensional grid of nodes. The number of nodes is larger than the swarm size and the species are allowed to move on the grid. The rule that defines the movement of the species through the grid is based on the similarity between the species' fitness values and the ranking of those same values within the entire population. Meanwhile, the fitness values are modified using the rules of a 2-dimensional Bak-Sneppen model. The system is intended to be a framework for metaheuristics with spatially structured populations and we show that it displays the desired characteristics for that purpose. Furthermore, these characteristics emerge as global patterns from the local interaction of the species. Without requiring the tuning of control parameters to precise values, the system seems to self-organize into a critical state between randomness and order.

## Introduction

*Self-organization* is a concept that includes a wide range of systems and dynamics. It is used in the realm of physics, chemistry, mathematics, biology and even in social sciences. In general, the term refers to a process through which a system increases its complexity without any external action. Although the complexity sciences have not yet devised a mathematical language that explains the origins and dynamics of self-organization, it may be stated that self-organization describes the property of systems whereby unexpected global patterns emerge from local rules. This paper presents a self-organized model of a population of simple entities that displays coherent global behavior emerging from local rules. The model was designed with the main objective of being applied as a dynamic and self-regulated base-structure for non-panmictic (or structured structured) population-based metaheuristics. The resulting system is a type of swarm intelligence – see Kennedy and Eberhart (2001).

Swarm intelligence algorithms are self-organized systems in which unsophisticated distributed entities interact locally, causing global patterns to emerge. The interaction may be

restricted to the communication between the entities, or it may use an environment as a medium for that communication. When the entities interact with (and via) the environment, the system is said to be *stigmergic*, a term introduced by Grassé (1959) to describe the ability of social insects in using the environment as a communication medium.

Fernandes et al. (2012) have recently described a new swarm intelligence discrete system with stigmergic local rules. The system consists of a population of  $n$  simple individuals (or particles) moving and interacting on a 2-dimensional grid of nodes. Stigmergy is modeled by providing the particles with the capacity of depositing and following *marks* that carry information about the particle. The structure is defined by local spatial neighborhood and results in a partially connected and dynamic grid of individuals. Each individual is assigned with a random value in the range  $[0,1]$ . This value is called *fitness*.

The motivation behind the work by Fernandes et al. (2012) is to create a dynamic framework for non-panmictic Evolutionary Algorithms (EAs), as defined by Tomassini (2005). EAs belong to a class of metaheuristics based on the Darwinian theories of evolution by natural evolution that use a population of possible solutions (individuals) to a problem. The population evolves by selection, recombination and mutation towards optimal regions of the search landscape. In panmictic EAs, every individual is allowed to interact with every other individual in the population. However, large-scale problems or deceptive functions with multiple local optima may require other type of structures. Therefore, in recent years, non-panmictic EAs, also known as *spatially structured EAs* (see Tomassini (2005)), are gaining increasing attention by the community. This class of EAs restricts the interaction according to a pre-defined or evolving structure that connects the population of solutions. They permit to control the genetic diversity of the population and avoid premature convergence, but they also require extra designing and tuning efforts. In addition, the chosen structure affects the connectivity and the performance of the algorithm.

One possible approach to overcome the rigid connectivity of the traditional structures without being trapped in complicated network design is to use the self-organizing and emergent properties of complex adaptive systems. The work by Fernandes et al. (2012) is an attempt to model the desired

characteristics of a dynamic and self-regulated population structure for non-panmictic EAs. In fact, complex properties, such as dynamic clusters of particles displaying pink noise patterns, have been observed while testing the model. However, the experiments in Fernandes et al. (2012) are restricted to a stationary version of the model, i.e., the fitness values of the individuals do not change during the run.

This paper extends the study by Fernandes et al. (2012) and investigates the behavior of the system when populations of time-varying fitness values interact on the grid and generate the structure. The rules for varying the fitness values were taken from the Bak-Sneppen model of co-evolution between interacting species, a complex system proposed by Bak and Sneppen (1993): in each time-step, the fitness value of the worst individual and the fitness values of its neighbors (if any) are replaced by random values in the range  $[0,1]$ . In other words, the worst individual and its adjacent neighbors in the habitat are mutated.

The Bak-Sneppen model is an example of Self-Organized Criticality (SOC), a theory that has been proposed by Bak et al. (1987) for explaining a class of systems that self-organize into a critical state without requiring the tuning of control parameters. When in the critical behavioral region, these systems display typical signatures, such as scale-invariance, power-law relationships between events and their intensity (or duration) and output variables with pink noise power spectrum.

The Bak-Sneppen model has all the above referred signatures. Like other SOC systems, it doesn't require parameters that need to be tuned. Furthermore, its global behavior can be described as a population of fitness values that evolve during the run. The average fitness of the population tends to grow and the gap  $G(t)$  of the system, which is the maximum of the minimum fitness before time-step  $t$ , is increased during the run until it reaches a specific range (that depends on the topology of the population). These characteristics make the Bak-Sneppen a good candidate for being implemented on the framework proposed by Fernandes et al. (2012) in order to investigate if the behavior observed in the stationary version is maintained in a population of time-varying fitness values. Moreover, the resulting model provides the opportunity to study a version of the Bak-Sneppen model that, to the extent of our knowledge, has not yet been proposed. This new version is characterized by a dynamic topology and by the self-regulated and hierarchical clustering of species.

In this paper, the experiments were designed for describing the properties of the new system, for analyzing the system's behavior in search for complexity and self-organization signatures, and for testing the robustness of the system to changes in the fitness distribution of the population.

The remainder of the paper is structured as follows. The following section addresses SOC and describes the original Bak-Sneppen model. Then, the proposed system is described and contextualized within the current research on spatially structured populations. The subsequent section describes the experiments and the system's dynamic behavior. The final section concludes the paper and outlines future lines of research.

## SOC and The Bak-Sneppen Model

SOC is a critical state formed by self-organization in a long transient period at the border of order and chaos. While *order* means that the system is working in a predictable regime where small disturbances have only local impact, *chaos* is an unpredictable state very sensitive to initial conditions or small disturbances. In complex adaptive systems, complexity and self-organization usually arise at that transition region between order and chaos, or *on the edge of chaos*, as it is sometimes stated. SOC systems are dynamical with a critical point at the region between order and chaos as an attractor. However, and unlike many physical systems, which have a parameter that needs to be tuned in order to obtain the critical state, SOC systems are able to self-tune to the critical point.

In a SOC system, small disturbances can lead to the so-called *avalanches*, that is, events that are spatially or temporally spread through the system. This happens independently of the initial state. Moreover, the same perturbation may lead to small or large avalanches, which in the end will display a power-law proportion between the size of the events and its abundance.

This means that large (catastrophic) events may hit the system from time to time and reconfigure it. These power-law relationships between the size of the events and their frequency are widespread in Nature. Earthquake distribution, for instance, follows the Gutenberg-Richter law, which is a power-law proportion between the magnitude of the earthquakes that occurred in a specific area during a specific period of time, and the frequency of those earthquakes. *Pink noise*, or  $1/f$  noise, also displays power-law behaviour (as opposed to *white noise*, which is chaotic).

One may distinguish three types of power-laws arising from physical systems. For instance, the power spectral density distribution (like the pink noise) is described by:

$$P(f) \propto \frac{1}{f^\alpha} \quad (1)$$

where  $f$  is the frequency,  $P(f)$  is the power of that frequency and  $\alpha$  is a real number between 0 and 2.0, but usually close to 1.0. If  $\alpha = 0$  then  $P(f)$  is named white noise; if  $\alpha = 2.0$  then it is named red noise or Brownian noise; when  $\alpha = 1.0$  then the function  $P(f)$  describes pink noise. In general, this function describes which frequency is the most dominant in the temporal behaviour of the system under consideration: the power spectral density is just the square of the Fourier transform of the signal under consideration.

Another power-law arises in size distributions (like the Gutenberg-Richter law, for instance):

$$N(s) \propto \frac{1}{s^\tau} \quad (2)$$

where  $s$  is the size of an event (or magnitude) and  $N(s)$  reflects a distribution of frequency of such events.

A third kind of power-law is identified in the temporal distribution of events, where  $\tau$  is either the duration of the event, or the time between events, as described by equation (3):

$$N(\tau) \propto \frac{1}{\tau^\nu} \quad (3)$$

SOC may be the common link between a wide range of natural phenomena operating at the region between order and chaos that exhibit these power-law relationships, a scale-

invariant behavior that does not need to be tuned. The first system where SOC was identified is a cellular automaton called *sand pile* and it is described by Bak et al. (1987). Later, Bak and Sneppen (1993) introduced the model of co-evolution between interacting species: the Bak-Sneppen model.

In nature, different species in the same eco-system are related through several features (food chains, for instance). They co-evolve, and the extinction of one species affects the species that are related to them, in a chain reaction that can reach huge proportions. Fossil records suggest that the size of extinctions events is in power-law proportion to its frequency. It is also known that the biological history of life on Earth is punctuated by catastrophic extinction events. The Bak-Sneppen model aims at understanding and explaining the mechanisms underlying mass extinction. It consists of a number of species, each one with a fitness value assigned and each one connected to other species (neighbors). Every time step, the species with the worst fitness and its neighbors are eliminated from the system and replaced by individuals with random fitness.

This description may be translated to a mathematical model. The system is defined by  $n^d$  fitness numbers  $f_i$  arranged on a  $d$ -dimensional lattice (ecosystem) with  $n$  cells. At each time step, the smallest  $f$  value and its  $2 \times d$  neighbours are replaced by uncorrelated random values drawn from a uniform distribution (in other words, the worst species is removed from the population and its neighbors are mutated). The system is thus driven to a critical state where most species have reached a fitness above a certain threshold and the avalanches produce non-equilibrium fluctuations in the configuration of the fitness values. The complex behavior is observed even in the one-dimensional case, where species are arranged in a chain, and each one has two neighbors.

Since its proposal, the model has been thoroughly investigated by the community and several extensions and modifications have been described. In the seminal paper by Bak and Sneppen, the research is focused on the 1-dimensional version of the system. Higher dimensional models have been since then investigated. De los Rios et al. (1998), for instance, study the high dimensional Bak-Sneppen model ( $d \geq 2$ ) and conclude that the system shows a rich behavior with four qualitatively different regimes as a function of dimensionality:  $d \leq 2$ ,  $2 < d < 4$ ,  $4 \leq d < 8$  and  $d \geq 8$ .

In this paper, we have used the rules of a Bak-Sneppen model with  $d = 2$ . However, the resulting system is not a standard 2-dimensional Bak-Sneppen model. In our model, the position of species is dynamic and the grid is partially connected, i.e., each species may have four or less species in its von Neumann neighborhood. This leads necessarily to a different behavior and the dynamics observed in the 2-dimensional model may not occur. However, we are mainly interested in the behavior of the proposed system as a potential framework for spatially structured EAs and therefore we search for signatures of dynamic clustering and robustness to changes. A theoretical analysis and empirical validation of the Bak-Sneppen model for determining critical exponents and the gap function is left for future work.

## The System

The proposed framework is a discrete system with a swarm of heterogeneous individuals controlled by a set of local rules. The rules define the actions of a population of  $n$  particles that move on a 2-dimensional toroidal grid of nodes with size  $X \times Y$ . In each time-step, every particle tries to move to a neighboring node. The rules that model the system are the following.

At  $t = 0$ , the particles are assigned a random *fitness* value in the range  $[0,1]$  and then randomly distributed in a  $X \times Y$  grid of nodes. Then, at each time-step, each particle moves to an adjacent free node (if any), leaving a mark with information on its status in the previous node. In this paper, the status is the fitness of the particle. The particles decide where to go by inspecting their Moore neighborhood. If there are no free nodes in the neighborhood (i.e., all the cells are occupied by particles), the particle stays in that same node until the next iteration. If there are free cells, the particle checks for marks. If it finds no marks, it just randomly chooses a destination node between the free neighboring nodes. If marks are found with better fitness than the particle's fitness, the particle moves to the node with the mark that minimizes the difference between its fitness and the fitness on the mark. Whenever a particle changes its position, it leaves a mark in its previous location. The marks only remain in the *habitat* for a time-step. In summary, communication by dropping and following information is the base-rule of the proposed system. The system is modeled with a stigmergic behavior.

The particles are ranked according to their fitness. This strategy is imposed with the objective of establishing a hierarchy in the self-organization of the clusters: worst particles tend to follow better particles (the better individuals are *leading the way*).

In each time-step (which comprises the update of every particle's position), the particle with lowest fitness is mutated (i.e., its fitness is replaced by a random value with uniform distribution within the range  $[0,1]$ ), as well as the fitness of its neighbors. The position of the neighbors is defined by the von Neumann neighborhood of the particle (with range 1). This is the standard Bak-Sneppen model on 2-dimensional habitats. The only difference is that in this case the number of neighbors of the worst particle that are also mutated is not necessarily  $2 \times d = 4$ . This is the maximum number of individuals that are mutated. If the worst particle is isolated (if there are no particles in its von Neumann neighborhood) there are no more mutations in that time-step except for the particle itself. Therefore, in each time-step,  $p$  particles are mutated, with  $p \leq 1 + 2 \times d$ .

This basic set of rules drives the system towards a dynamic global pattern that displays signs of self-organization. A structure of particles, formed by clusters and paths, emerges on the habitat. However, these clusters are far from being static and, in a few generations, the distribution of the whole swarm may change dramatically (while maintaining a typical configuration of clusters and paths). The swarm's behavior is not ordered (nor chaotic). Please remember that convergence to a behavioral region between order and chaos is a signature of self-organization.

---

**Algorithm**

---

1. Randomly place  $n$  particles in a grid of node with size  $X \times Y$
  2. Randomly attribute a fitness value to each particle
  3. Find the particle with the lower fitness value. Mutate its fitness and the fitness of its neighbors (von Neumann neighborhood).
  4. Rank the particles by increasing fitness
  5. For each particle do
    6. check Moore neighborhood for marks and other particles
    7. if no marks in the neighborhood
      8. move to a free cell in the neighborhood (if any)
    9. if there are marks in the neighborhood
      10. move to the site of the nearest fitness mark which is better than its own fitness
      11. leave a mark in the previous site
      12. erase the mark in the new site
  13. if stop criteria not met return to 3
- 

Besides dynamic clusters, there are other signatures that suggest that the model comprises a *hidden order* that emerges from local rules. The following section tries to detect and describe those signatures under static and dynamic populations.

Please note that the only parameters that need to be set are the population size  $n$  and the grid size. If the ratio between  $n$  and the grid size is set within a specific range (large enough to allow communication between the particles, while not so large so that the particles hardly move on the grid), the system self-organizes without requiring the tuning of control parameters. The following section shows that dynamic global patterns emerge within a wide range of population and grid size values. But first, let us discuss the motivation behind the proposed model.

### Motivation

Genotypic representation, operators, selection schemes and population size are typical panmictic EAs moduli that require design choices. However, a population structure may be also introduced in the design scheme of this class of algorithms. This structure specifies a network of acquaintances for individuals to interact, that is, mating or selection is restricted to neighborhoods within the network structure. Spatially structured EAs include fine-grained approaches such as cellular EAs and course-grained approaches such as island models.

The initial objective of spatially structured EAs was to develop a framework for studying massive parallelization – see Gordon and Whitley (1993). Afterwards, the need to provide traditional EAs with a proper balance between exploration and exploitation motivated several lines of research that explore the potentiality of different population structures in maintaining genetic diversity. Population structures were primarily devised as static regular lattices: every individual has a fixed number of potential interaction partners. Later on, complex population structures have been also studied – by Giacobini et al. (2005) and Payne and Eppstein (2006), for instance. However, these standard *cellular EAs* have some drawbacks: synchronicity (in most cases) and a strong dependence on the problem since the

genetic diversity promoted by a prefixed topology is uncorrelated to the problem structure.

Dynamic population structures have only recently raised the interest of researchers. To the extent of our knowledge, only few works address explicitly the issue of dynamic population structures in cellular EAs. Alba and Dorronsoro (2005) dynamically change the ratio that defines the neighborhood of interaction. Since the ratio may affect selection pressure, the authors analyze its influence on the balance between exploration and exploitation. However, the base-structure of the cellular EA (i.e. a grid lattice) is maintained throughout the run.

Whitacre et al. (2008) focus on two important conditions missing in EA populations: a self-organized definition of locality and interaction epistasis. With that purpose in mind, they propose a dynamic structure and conclude that these two features, when combined, provide behaviors not observed in the canonical EAs or traditional spatially structured EAs. The most noticeable change in the behavior is an unprecedented capacity for sustainable coexistence of genetically distinct individuals within a single population. The authors state that the capacity for sustained genetic diversity is not imposed on the population; instead, it emerges as a natural consequence of the dynamics of the system.

Laredo et al. (2010) propose a framework for EAs based on peer-to-peer networks (see Steinmetz and Wehrle (2005) for a survey on peer-to-peer networks). Within a simulated environment, they model the dynamics of real networks and conclude that their system is able to achieve better performance than traditional EAs on a wide range of problems, while being scalable and resilient to the volatility of nodes in the network.

The work by Fernandes et al. (2012), extended in this paper with a Bak-Sneppen model, has some minor similarities to that by Whitacre et al. (2008), since the structural characteristics of complex systems within an EA population are also recreated. However, while in Whitacre et al. (2008) the structure co-evolves with the EA until it reaches a stable self-organized state, the system described here does not converge to rigid or nearly-rigid state. Instead, it aims at a system working in a critical state where links are frequently created and destroyed and where new emergent patterns appear at high rate.

We demonstrate that the proposed system has indeed emergent properties that could prove useful for spatially structured EAs, or other spatially structured population-based metaheuristics. In this paper, the dynamics of the system and its self-organizing behavior are studied under dynamic populations: the fitness values vary through the run according to the rules of the Bak-Sneppen model. Such dynamics are intended to model the behavior of EAs on the proposed framework. Therefore, it is expected that the outcome of the experiments can provide information on the self-organizing properties of the system and on the limits of those properties.

## Experiments and Discussion

This section investigates the dynamic behavior of the system. Visual descriptions of the patterns that emerge from the interaction of the particles are given. Output patterns are analyzed in search for self-organization signatures. The

degree of clustering throughout the entire run is inspected, as well as the distance of the particle to their neighbors (measured in variation between fitness values).

The system was tested with stationary and time-varying populations. The experiments with static populations have been described by Fernandes et al. (2012); therefore, in this paper we only give an overview of the results and conclusions in that study in order to contextualize the discussion. The stationary model is described by the pseudo-code given in the previous section after removing step 3.

The main goals of this section are: 1) check if the self-organizing properties are maintained with time-varying fitness values; 2) investigate the properties of the dynamic and partially connected Bak-Sneppen model and compare it to the standard models.

**Figure 1.** Space-time diagrams of a 1-dimensional habitat.  $X \times Y$ :  $150 \times 1$ . Swarm: 25, 50 (top to bottom).

### Stationary Fitness Values

Although the model has been designed has a 2-dimensional framework for EAs, the 1-dimensional version may be constructed by setting  $X$  or  $Y$  to 1 (see the pseudo-code in the previous section). The 1-dimensional version displays interesting and complex behavior, has shown in Figure 1. The graphics represent the space-time diagrams of the system. These diagrams are usually used to track the spatial configuration of a cellular automaton over a number of time-steps. In this case, the diagrams may illustrate the chaotic and order factors of the system.

Results with grid size  $150 \times 1$  and  $n = 25$  and  $n = 50$  are shown in Figure 1. The leftmost row of the cells is the 1-dimensional lattice set up with a random initial distribution of particles. Each successive row going right is the updated lattice at the next time step. The diagrams show a mixture of order and randomness which is typical, for instance, of class 4 cellular automata. Some clusters of particles move up or down, while free particles randomly move through the grid until they are “captured” by a cluster. Meanwhile, clusters disaggregate, freeing more “wandering” particles. These are typical signatures of complexity and activity between order and randomness. If these traits emerge in a 1-dimensional environment, it is expected that, at least, a similar degree of complexity is present in the 2-dimensional system.

In order to investigate the 2-dimensional model, the grid was then set to  $60 \times 60$  and the swarm size to 1200 (meaning that the ratio between particles and nodes is 1:3).

Figure 2 depicts the distribution of the particles on the grid at different time-steps between  $t = 0$  and  $t = 1000$ . The

**Figure 2.** Position of particles and average degree of clustering  $k$ .  $X \times Y$ :  $60 \times 60$ ;  $n = 1200$ .

average degree  $k$  of clustering is given. This variable measures the number of particles in each particle’s Moore neighborhood. The average  $k$  is the degree value averaged over the entire population.

The images in Figure 2 show that the particles are able to self-organize into a dynamic structure of clusters and paths. This assumption is confirmed by the  $k$  values, which, starting from  $k = 1.18$ , tend to grow, reaching 4.02 after 1000 iterations. The graphics also confirm that the particles do not only aggregate in small clusters, they also form trails between the clusters. In fact, in most of the time-steps, large parts of the population are connected. This is a key result for the project of designing a dynamic self-organized framework for spatially structured EAs, since information may flow quickly through the population.

Another important outcome is observed in the snapshots of later iterations. Averaged  $k$  is similar at iterations 750 and 1000. In fact, at this later stage,  $k$  does not tend to increase. However, the distribution of the particles is clearly different in the two *snapshots* of the system. That is, even after converging to the maximum range of  $k$  values, the swarm continues to reorganize and reshape the clusters. The system is in a state of dynamic equilibrium. Clusters form, but they may disaggregate at any moment, and the particles move to another region of the habitat where they will cluster again with other particles.

Figure 3 shows the distribution of fitness values on the grid by plotting the particles with a grey-level proportional to their fitness. Comparing the distributions at an early and later stage we see that the particles do not only self-organize into clusters; they also tend to cluster according to the fitness, creating structures of particles with similar fitness.

A quantitative analysis of the system was conducted by investigating its output variables, namely the average degree of clustering  $k$  and the average distance  $d$  to the neighbors. The Fourier Transform of  $k$  and  $d$  was calculated for a representation of the signal in the frequency domain. For the Fourier Transform, 4096 samples of the signals were used, from  $t = 1000$  to  $t = 5095$ . This way, the spectral density leaves out the transient phase, from the random configuration at  $t = 0$  to the self-organized state. The observation and analysis of the spectral density showed that large regions of the spectra are reasonably approximated by power-laws.

The power spectra were plotted in log-log coordinates, as is customary, since the logarithmic transform renders the power spectrum a straight line whose slope can be easily estimated. The slope  $\alpha$  of the power-law in both cases was found to be close to 1, which is the slope of pink noise. The more general case, which displays a spectral density  $S(f) = \text{constant}/f^\alpha$ , where  $0 < \alpha \leq 2$ , is sometimes referred simply as  $1/f$  noise.

**Figure 3.** Distribution of fitness values on the grid. Lighter grey areas correspond to particles with lower fitness.  $X \times Y$ :  $60 \times 60$ ;  $n = 1200$ .

If we investigate the spectrum of  $k$  and  $d$  that emerges from a random structure, we find an almost flat density, a signature of white noise. The stigmergic rule supply the system with a typical trait of complex adaptive system and self-organization in near-equilibrium state between order and chaos.

Table 1 show the slopes of the power-laws used for fitting the data obtained by different ratios between the grid size and the number of particles. The relationship between intensity and frequency of  $k$  and  $d$  is similar when the ratio is in the range  $[1:24, 1:2]$ . Outside this range,  $\alpha$  tends to decrease. This is an expected result, due to the physical constraints of the system. On one hand, the swarm requires critical mass to interact. On the other hand, the particles require space to move. However, the model seems to be robust. In order to study its robustness, the swarm was tested with a fixed ratio between the population size and the number of nodes. Several combinations of  $n$  and grid size were used. The slopes of the power-laws used for fitting  $k$  and  $d$  spectrum are in Table 2. With  $n = 33$  the slope of the power-law decreases, but for  $n > 33$  the power-laws are very similar. The properties of the signals are stable for three orders of magnitude. The system is robust as long as the ratio is within a specific range. The complete description of these experiments, as well as other details on the results with the stationary version of the model, are given by Fernandes et al. (2012).

Table 1. Slope  $\alpha$  and  $r$ -squared of the power-law that fits the  $k$  and  $d$  spectral density for different ratios between  $n$  and the number of nodes on the grid ( $X \times Y$ ).

$n: \text{nodes} \rightarrow$	1:24	1:12	1:6	1:3	1:2	1:1.5	1:1.2
$k$	1.18 (0.76)	1.23 (0.76)	1.23 (0.76)	1.20 (0.76)	1.07 (0.70)	0.88 (0.60)	0.56 (0.60)
$d$	0.82 (0.60)	1.00 (0.72)	0.97 (0.68)	1.01 (0.69)	1.00 (0.69)	0.93 (0.64)	0.42 (0.60)

Table 2. Slope  $\alpha$  and  $r$ -squared.  $n: \text{nodes}$  is fixed and equal to 1:3.

$n \rightarrow$	33	75	147	300	616	1200	2408	4800

$d$	0.87 (0.62)	1.04 (0.70)	1.04 (0.71)	1.10 (0.75)	1.03 (0.70)	1.01 (0.69)	1.02 (0.69)	0.97 (0.69)

## Time-Varying Fitness Values

In this paper, the model was tested with the Bak-Sneppen mutation rules (i.e., including the step 3 of the pseudo-code given in the previous section). The size of the grid was set to  $60 \times 60$  and the swarm is comprised of 1200 individuals.

The first analyses aim at comparing the behavior of the system with stationary and non-stationary fitness values. For that purpose, the spectra of the output variables ( $k$  and  $d$ ) were computed and compared with the spectral densities of the stationary version.

Figure 4 compares the spectral density of the average distance between neighboring particles in each time-step. The introduction of the mutation rules based on the Bak-Sneppen model does not affect significantly the distribution of frequencies.

Figure 5 shows the spectral density of the connectivity degree  $k$ . Again, introducing a mutation mechanism in the original model does not affect the general behavior of the swarm and the clustering dynamics. These results demonstrate that it is possible to obtain an emergent behavior consisting of dynamic clustering based on similarity and hierarchy using not only a population of stationary fitness values, but also an evolving population. This is an important result since an EA, by definition, is a population of solutions that, in average, improves over time. If an EA is implemented on a population of the model, and if the intensity of changes is maintained within a certain boundary (here, the number of fitness values that change in each time-step is in the range  $[1,5]$ ), it is expected that global patterns that emerge from the proposed model also appear in the model-based EA.

**Figure 4.** Comparing the spectral density of the average distance  $d$  that emerges from the stationary and non-stationary fitness versions of the model.

**Figure 5.** Comparing the spectral density of the average connectivity degree  $k$  that emerges from the stationary and non-stationary fitness versions of the model.

The evolution of the population can be visualized by plotting the average and minimum fitness of the population, as well as the gap function  $G(t)$ . Figure 6 shows the evolution of 1200 particles on a  $60 \times 60$  grid, while Figure 7 shows the evolution of a population of 1200 on  $30 \times 40$ , i.e., Figure 7 displays the behavior of a standard 2-dimensional Bak-Sneppen model. The average fitness of the partially connected model evolves to higher values. The proposed model reaches an average fitness values of approximately 0.8, while the standard 2D model stays below 0.7 (a result observed in several runs with different random seeds).

The gap function also grows faster and reaches higher values. In the several runs conducted for this study, the critical value of the gap function was found to be  $f_c \sim 0.6$ . The dynamics of the proposed model is clearly different from the standard 2D model. The sparser connection between the particles is a reasonable explanation for the differences in the evolutionary rates (please remember that in our model there are  $p \leq 1 + 2 \times d$  particles that are mutated in each time-step, while in the standard 2D Bak-Sneppen model there are  $p = 1 + 2 \times d$  mutations). The effects of the local movement rules are harder to measure, but since the particles cluster according to the fitness values, better particles tend to gather in the same regions, and therefore the mutation of the worst individuals will tend affect also *weak* neighbors, thus leading to a faster evolution of the population's fitness values.

One of the SOC signatures of the Bak-Sneppen model is the power-law relationship between the duration of the species' periods of stasis (time-steps between successive mutations) and their frequency. The proposed model displays

**Figure 6.** Evolution of 1200 particles on a  $60 \times 60$  grid. Average fitness, minimum fitness and gap function.

**Figure 7.** Evolution of 1200 particles on a  $30 \times 40$  grid (standard 2D Bak-Sneppen model).

the same signature. The exponent of the power-law is approximately  $3/2$ , as seen in Figure 8. This is the same exponent obtained with the standard 2-dimensional model, while the 1-dimensional Bak-Sneppen system, in our experiments, displays a power-law with exponent approximately  $7/4$ .

The model maintains the characteristics of the stationary version proposed by Fernandes et al. (2012). Global patterns of clusters connected by paths tend to emerge. These clusters are highly dynamic, and in a few generations the distribution of the particles in the habitat may dramatically change (we believe there is an avalanche-based self-organized phenomenon behind the massive reconfigurations of the system but we haven't yet identified it). The output variables of the system display pink noise spectral densities. Furthermore, the proposed model maintains the characteristics of standard 2-dimensional Bak-Sneppen models. The average fitness of the population tends to grow with time, and the gap function converges to a specific critical value. The power-law observed in the distribution of distances between successive mutations also appears in the proposed model, with the same exponent as the 2-dimensional Bak-Sneppen model.

## Conclusions and Future Work

This paper describes an evolutionary extension of the self-organized swarm intelligence system proposed by Fernandes

**Figure 8.** Duration of the periods of stasis (periods in-between mutations).

et al. (2012). The system is a swarm of simple particles that interact on a heterogeneous grid of nodes. The particles communicate via the grid, and move according to simple rules. A fitness value is assigned to each particle. In each time-step, the fitness values of the worst particle and its neighbors are mutated. This is the basic rule of a Self-Organized Critically (SOC) model known as the Bak-Sneppen model of co-evolution between interacting species.

The system has been designed as a base-framework for spatially structured Evolutionary Algorithms (EAs). The original model (without the Bak-Sneppen mutation rules) displays a complex behavior illustrated by dynamic clustering of the particles, catastrophic reconfigurations of the distribution of the particles on the grid, and output variables with pink noise spectral densities. The model proposed in this paper maintains the main characteristic of the stationary fitness values version. This conclusion is very important for the project of designing a spatially structured framework for EAs based on the proposed system. Furthermore, the system

displays the same SOC signatures as the standard 2-dimensional Bak-Sneppen model.

In the future, the research will be focused on two main lines of work. Firstly, an EA will be implemented on the model and compared to standard spatially structured EAs. Secondly, the behavior of the system as an (hypothetical) SOC system will be studied. Traits such as the critical fitness threshold and the critical exponents of the model will be investigated. Furthermore, we believe that there is an avalanche-based phenomenon triggering the massive reconfigurations of the system (particles' positions on the grid). In a future research, we will try to identify that phenomenon, its origin, and study its distribution in search for self-organization signatures.

## Abstract

Co-evolution of predators and prey is an example of an evolutionary arms race, leading in nature to selective pressures in positive feedback. We introduce here an artificial life ecosystem in which such positive feedback can emerge. This ecosystem consists of a 2-dimensional liquid environment and animats controlled by evolving artificial gene regulatory networks encoded in linear genomes. The genes in the genome encode chemical products which regulate other genes, sense the environment (the scent of food, prey and predators), control the animat's movement, and its foraging strategy. An animat can switch multiple times in its life between two foraging strategies (with different metabolic costs): a predator can derive food from the prey, prey just from food that diffuses in the environment. When an animat consumes enough food (or prey), it produces an offspring with a mutated genome. Mutations introduce variation into the population, and this diversity together with selective pressures leads to the evolution of control for diverse foraging strategies in an ecosystem that can support hundreds of individuals.

## Introduction

The ability to prey on other organisms is a distinguishing feature of animals, and multi-level complex relationships between predators and prey are the building blocks of ecosystems. Prey-predator relationships create coupled selective pressures which can lead to evolutionary arms races between genes and lineages (species). Examples of artificial ecosystems in which such pressures exist include “sticky-feet” (Turk, 2010), in which simple multicellular organisms could both be prey and be preyed upon, and systems where separate lineages of prey and predators co-evolved, such as “Spiders” (Palmer and Chou, 2012), and “Bubbleworld” (Schmickl and Crailsheim, 2006).

In biology, prey-predator relationships evolve even between the simplest, one-celled organisms. The behaviour of these single cells is controlled by gene regulatory networks: networks in which a node represents a gene (or co-expressed genes) and edges represent regulation relationships—a directed edge from one node to another means that the product of one gene regulates the expression of another, often

because this product binds physically (thanks to chemical affinity to DNA) in the vicinity of another gene. Gene products play not only regulatory roles, but also catalyse chemical reactions in the cell, form intracellular or extracellular structures, including structures necessary to sense the changes in the environment or necessary to allow for cell movement.

In our previous work we evolved artificial gene regulatory networks—using a genetic algorithm, or a novelty search algorithm (Lehman and Stanley, 2011)—to process signals (Joachimczak and Wróbel, 2010), direct multicellular development (Joachimczak and Wróbel, 2008, 2012b), and control the behaviour of unicellular (Joachimczak and Wróbel, 2009) and multicellular animats (Joachimczak and Wróbel, 2012a). Other models of artificial gene regulatory networks have been evolved to match mathematical functions (Kuo et al., 2004), evolve biological clocks (Knabe et al., 2006), study dynamics of gene expressions (Reil, 1999), and evolve robot controllers (Reil, 1999; Quick et al., 2003), also using genetic algorithms and objective fitness functions. But a genetic algorithm or a novelty search algorithm is a very imperfect model of biological evolution. In biology there is no objective fitness function—fitness corresponds to the number of offspring that is produced, and can be construed as the ability to use the resources in the environment to do so.

Because the resources of the environment are always limited, the organisms compete for them, and offspring resembles parents but also varies, natural and artificial ecosystems can be analysed from the point of view of flows of energy/matter on a short time scale and from the point of view of information on how to use the resources (evolution) on the long times scale. Artificial ecosystems are very far from capturing the complexity of matter and energy transformations in Nature or the complexity of the evolutionary process (for a review, see Dorin et al., 2008). In this paper, we present a simple system in which artificial organisms (animats) obtain matter/energy from the environment and evolve. The animats metabolise food, producing waste. Matter and energy derived from food allows them to move and to produce offspring. Animats can sense the concentra-

tion of food and waste produced by other animats, and use this information to direct movement. Offspring receives a mutated genome from the parent, allowing for evolution.

The system we present here is an extension of our previous work, in which we coupled our Gene Regulatory evolving artificial Networks (GReaNs) artificial life system with a physically plausible model of a 2-dimensional liquid environment in which thousands of animats can evolve foraging behaviour (Erdei et al., 2012). The main contribution of the work here is the introduction of a simple metabolism and a model of animats that can switch their strategy from a predator to prey and vice versa. We show here a preliminary analysis of the evolutionary trajectories and of the evolved life strategies in our artificial ecosystem.

## 2-dimensional liquid environment with foraging animats and diffusible substances

Simulated organisms (animats) live and evolve in a toroidal 2-dimensional liquid environment. The world contains three diffusible substances: (i) food (a source of energy) diffuses from multiple points in the environment and also from killed prey, (ii) scent of prey, and (iii) scent of predators. The last two can be seen as waste products of the prey or predator cells and allow other cells to sense them. To allow for computationally efficient yet realistic simulation of diffusion, concentration of all substances is stored using a quadtree (Finkel and Bentley, 1974) in which the root node represents the whole environment, and the other nodes – subregions of this space. Each square subregion can be divided into four smaller and equal subregions, and thus each node can have exactly four children. The depth of the tree is higher for regions where either the concentration or the gradient of concentration is high (there is a separate quadtree for each substance). Places where animats are located are always represented by squares of minimum allowed size (1 length unit squared). In each subregion the chemical gradients are continuous, calculated using bilinear interpolation (Fig. 1, Gribbon and Bailey, 2004); to simplify this calculation, we permit only two kinds of neighbourhood: the neighbouring squares are of the same size or the bigger neighbour borders exactly 2 smaller squares, each one 4 times smaller in area than the bigger square.

Diffusion of substances between two adjacent squares follows the Fick's law:

$$\Delta P = \frac{c \cdot d}{D} \cdot (S_2 - S_1) \cdot \Delta t, \quad (1)$$

where  $\Delta P$  is the amount of food by which the concentration will increase in the next step in square 1 and decrease in square 2 (provided that the current concentration is greater in square 2 than square 1),  $c$  is the coefficient of diffusion (0.1 for food, and 0.25 for scent in the experiments described here),  $d$  is the length of the common edge,  $D$  is the distance between the centres of the squares,  $S_1$  and  $S_2$  are the current

Figure 1: Modelling diffusion in 2-dimensional environment using a quadtree with continuous gradient of diffusible substances. The concentration is represented as a shade of grey, scaled linearly in the left panel and logarithmically in the right one; white corresponds to the maximum concentration close to the sources (bright squares). Animats (white circles) sense interpolated value of concentration at their exact location.

concentrations in both squares, and  $\Delta t$  is the duration of the simulation step. Since each square stores the concentration (not the amount), the concentration in square X is changed by  $\Delta S = \frac{\Delta P}{A_X}$ , where  $A_X$  is the area of square X.

At every time step, substances not only diffuse, but also degrade exponentially:

$$S(t_0 + \Delta t) = S(t_0) \cdot g^{\Delta t}, \quad (2)$$

where  $S(x)$  is the concentration of the substance in given square in time  $x$ ,  $\Delta t$  is the duration of the simulation step,  $g$  is the degradation coefficient (0.99 for food, 0.9 for scent), and  $t_0$  is the previous moment of time. Changes in concentration caused by diffusion and degradation make square areas split or merge, changing the quadtree.

## One-celled predators and prey controlled by gene regulatory networks

Each animat in our system has one cell; all have equal size, shape (a circle 1 length unit in diameter), two actuators and six sensors (Fig. 2). Each sensor provides the information on the concentration of one of the following substances: food, predator scent, and prey scent (a pair of sensors for each substance) at the sensor's location. An actuator generates thrust, and because we consider our animats as models of single cells, we use a word 'flagellum' when referring to actuators (but they can be thought of as thrusters or motor-driven wheels). The activity of each actuator is controlled in a continuous fashion, so the animats can go forward or rotate in the chosen direction by varying the level of activation of the actuators. The animats move faster (accelerate by  $\frac{\text{distanceUnit}}{\text{timeStep}^2}$ ) when both flagella are fully activated, or rotate faster (by  $\frac{1\text{rad}}{\text{timeStep}^2}$ ) when one flagellum is fully activated and the second one is not activated at all. The maximum

Figure 2: One-celled animat with six sensors (circles; each circle is the position of 3 sensors, one sensor for each substance in the system) and two actuators ('flagella'; triangles). The front of the animat is on the top of the figure.

speed is limited by drag (linear and angular) proportional to the velocity squared.

The concentration of food ( $S$ ) in the square where the centre of the animat is located determines how much food it consumes:  $0.75 \cdot S \cdot 1vu$ , where  $1vu$  is 1 volume unit. The food is stored internally and used up as follows:

$$\Delta M_t = (M_b + M_m \cdot \frac{a_1 + a_2}{2} + Z \cdot M_p) \cdot \Delta t, \quad (3)$$

where  $\Delta M_t$  is the total metabolic expenditure (by which the internal store is depleted in each time step),  $M_b$  is the base level metabolism (0.003 food units),  $M_m$  is the metabolic cost of movement (0.004),  $a_n$  is the current activation level of  $n^{th}$  flagellum (the minimal activation of a flagellum is 0, the maximum level is 1),  $Z$  is current state (prey have  $Z = 0$ , predators have  $Z = 1$ , and so does a prey cell undergoing a change into a predator; this change takes 20 simulation time steps), and  $M_p$  is metabolic cost of predation (in various experiments, we used 0.005, 0.010, or 0.015 for  $M_p$ ).

An animat can choose either to feed only on the food diffusing in the environment (and run the risk of being preyed upon) or to be a predator (and have a higher cost of metabolism, which can be seen as the cost of maintaining cellular structures necessary for killing the prey and feeding of other predators; in our system predators cannot feed on other predators). The switch between these two feeding strategies depends on the internal level of a chemical product encoded by the genome (Fig. 3). This concentration can change (in 0-1 range) during animat's lifetime, so multiple such strategy switches are possible (every time a threshold of 0.5 is passed).

The fact that each switch takes time (20 time steps) prevents the evolution of a strategy to change the state in response to prey or predators nearby. Depending on the state, an animat emits either a predator or prey scent. Only the collisions between predators and prey are detected, otherwise two animats in the same state (e.g., two prey cells) can overlap. Because the area of the world is large (in comparison to the average number of individuals), such overlaps happen rarely. If a prey cell is touched by a predator, the prey dies, provides 4 units of food to the predator, and whatever food was stored in its internal store to the square in which the prey cell was located.

Figure 3: The possible changes between animat states. Depending on the state of its gene regulatory network, the state of the animat can change from prey (white square) to predator (yellow square; the red cross marks the state in which an organism can kill prey and cannot be killed) and vice versa, through temporary states (circles) that last 20 simulation steps. In a state marked by yellow the animat emits a predator scent, otherwise it emits prey scent.

The amount of food stored in the internal store determines if the animat is viable or can produce offspring. When the store drops to 0, the animat dies and 3 food units are released to the grid square occupied by the dead cell. When, on the other hand, there is more than 7 units of food in the store, an animat can produce one offspring cell. The cost of producing offspring is 4 units; the rest of the food in parent's store is divided equally between two cells. The new animat inherits the state of the gene regulatory network and its prey vs. predator status from the parent, it cannot change this status for the next 20 time steps to prevent a parent from immediately killing the offspring or vice versa.

Artificial gene regulatory networks that control animats' behaviour are encoded in linear genomes as described previously (Joachimczak and Wróbel, 2008). The network can be represented by a graph in which nodes correspond to chemical products in the system and the edges correspond to regulatory relations. All the products can have continuous concentrations (the minimum concentration is 0, the maximum is 1), with the exception of one special product whose level is always 1. This product serves the same role as the bias input in artificial neural network. There are 6 other input products; the concentration of these products depends on the activation of the sensors, and there are two products for each chemical substance diffusing in the environment (food, predator scent, prey scent). The concentration of one product ( $i_{dif}$ ) in each pair depends on the difference in the concentration of a substance sensed by the right sensor and the concentration sensed by the left, detecting even small gradients across the body:

$$i_{dif} = \frac{1}{7.5} \cdot \log_{10}(|s_{right} - s_{left}|) + 1, \quad (4)$$

where  $s_{right}$  and  $s_{left}$  are the concentrations of the substance detected by sensors. The concentration of the second special product ( $i_{avg}$ ) in each pair depends on the mean concentration sensed on the right and left:

$$i_{avg} = \frac{1}{7.5} \cdot \log_{10}\left(\frac{s_{right} + s_{left}}{2}\right) + 1, \quad (5)$$

Apart from 7 input products, there are 3 output products: 2 control directly the activity of the two flagella, one determines whether an animat is currently a predator or a prey.

The topology of the regulatory network is encoded in a linear genome, which is a list of genetic elements. Each element stores 4 numbers: a type of the element, a sign, and 2 coordinates. There are 4 possible types: regulatory, coding, input, and output. Coding elements and inputs define products that have affinity to regulatory elements. A series of regulatory elements followed by a series of coding elements is a regulatory unit. An output element is a regulatory unit by itself, as if it was a regulatory unit with one regulatory element (with the sign and coordinates of the output element) and a virtual coding region coding a product that does not have affinity to any regulatory elements. Regulatory units and inputs correspond to nodes in the graph that represents the networks; the edges are defined by affinities. The affinity between two elements is determined by their coordinates. Each element defines a point in a 2-dimensional abstract space (which has nothing to do with the 2-dimensional liquid environment in which the animats move). The affinity is maximum if two points overlap, and decreases with the Euclidean distance between points, reaching zero if the distance is more than 5. If  $K$  products have affinities to the  $J$  regulatory elements of a regulatory unit, the concentrations of all products belonging to this unit  $L_{\Omega}$  will change depending on the affinities (Euclidean distances,  $d_{k,i}$ ) and concentrations of the regulating products in the previous step ( $L_k$ ):

$$L_{\Omega} = \frac{2}{1 + e^{-(\sum_{j=1}^J \sum_{k=1}^K L_k (m_k \cdot m_i \cdot \frac{10-2d_{k,i}}{10d_{k,i}+1}))}} - 1, \quad (6)$$

While the concentrations of products change during animat's life, the topology of the network (the number of nodes and edges) does not. It only changes when an offspring is produced — the parent keeps the old genome, the offspring receives a mutated copy, so genomes that encode individuals who manage to reproduce are maintained in the population (similarly to the microbial genetic algorithm; Harvey, 2011). There are 2 types of mutations that change the offspring genome: simple mutations acting at the level of a single genetic element and complex mutations, acting at the level of the whole genome. There are 3 types of simple mutations, each can occur independently, with probability 0.01: change of type, change of sign, and change of coordinates (each coordinate is modified by a random value

from a normal distribution with  $\mu = 0$ ,  $\sigma^2 = 5$ ). Complex mutations—deletions and duplications—happen each with a probability of 0.002 per genome; the number of genetic elements removed or copied after a randomly chosen element is drawn from a geometric distribution (with a mean of 10).

## Evolution of foraging strategies in an artificial ecosystem

We started each evolutionary run from 1 000 animats with randomly generated genomes consisting of 10 regulatory units (with 1 regulatory and 1 coding element in each), 3 outputs, and 7 inputs. At the start of each run, the animats had random locations in the environment 256 length units across. Each evolutionary run continued for 3 000 000 time steps, and the amount of food sources decreased linearly in time from 64 (a number high enough for the animats with random genomes to survive) to 24 at the end (increasing the selection pressure). Each food source provided 0.2 food units per time step, starting from the initial 60 food units, except for the first 64 sources, which had between 1 and 60 food units initially (a number drawn from a uniform distribution), otherwise sources would be depleted periodically. We replaced depleted source with new ones at new random locations.

We have simulated evolution for 36 independent runs in total, 12 runs for 3 values of metabolic cost of predation ( $M_p$  in Eq. 3): 0.005, 0.010, and 0.015; we kept other parameters without change (Table 1). Our previous results for the situation without predation (Erdei et al., 2012) indicate that evolution of foraging is efficient. Is it equally so in the presence of predators? How the metabolic cost of predation influences the efficiency of animats' strategies? Do animats evolve to track prey or avoid predators?

When the metabolic cost of predation was 0.015, in all the runs there were animats at the end of the run, but the lower was the cost, the higher was the chance of a population dying out (Fig. 4) with decreasing food availability over time. In particular, half of the runs with the lowest cost died out around time step 200 000, so we removed these runs from further analysis, and we show the other results only up to step 2 000 000, when the populations started to die out for the intermediate cost (all the trends we discuss, however, continue beyond this time point with no qualitative changes).

The number of individuals stabilized each time the number of food sources decreased (Fig. 5b), suggesting that the animats adapt to the new environmental conditions. When we tested the animats with random genomes in the environment with 24 food sources, they were not able to survive, indicating evolution of efficient foraging.

For the runs with the highest metabolic cost of predation, the final number of predators was small, but temporarily—when the food availability was still high—the environment supported more predators than prey (Fig. 5a). On the other hand, when the cost was 0.005 it did not pay to be prey—

Table 1: Parameters of the environment and animal metabolism in evolutionary experiments

parameter	value
food degradation coefficient	0.99
food diffusion coefficient	0.1
scent degradation coefficient	0.9
scent diffusion coefficient	0.25
duration of state change	20 time steps
no state change after division	20 time steps
base level metabolism	0.003 food units
metabolic cost of movement	0.004 food units
metabolic cost of predation	0.005, 0.010 or 0.015 food units
metabolic cost of reproduction	4 food units
reproduction threshold	7 food units
world size	256 square length units
length of evolutionary runs	3 000 000 time steps
food sources	64 to 24, decreasing with time
initial size of food sources	60 food units
source depletion rate	0.2 food units per time step

the average amount of prey in 12 runs decreased almost to 0—and when the cost was 0.010, the amount of prey was temporarily driven almost to zero, before at average it stabilized at a low level (Fig. 5a). For the intermediate cost, however, the total number of animats was the smallest (Fig. 5b), and the average amount of food stored in the animats' internal stores (amount of eaten food minus metabolic costs) per time step was the lowest (Fig. 5c), suggesting that resources were channelled to tracking prey or to avoiding predators. The amount of food stored per step was the highest when the metabolic cost of predation was the highest; because the animats avoided changing to predators, they did not suffer this higher cost at all.

We analysed in detail the behaviour of several individuals from the final populations evolved under the intermediate

Figure 4: A number of evolutionary runs containing at least one animal as a function of time for three different values of the metabolic cost of predation.

metabolic cost of predation, by manual tracking of hand-picked individuals. This preliminary analysis suggests that a form of predator avoidance evolved in these conditions; although prey animats moved towards food sources, they avoided doing so when there were predators near the source. This strategy was efficient late in evolution because at this point prey was able to store enough food (in the internal store) to survive when searching for a food source without predators. If a prey individual moved, however, towards a source occupied by predators, it usually changed to a predator on the way. Although this change incurred a metabolic cost of producing defenses against other predators, it would pay out because high predator scent in a small area close to the source would not allow for efficient predator avoidance. On the other hand, we did not observe any predators that chased prey, even though prey did not move at full speed, and though it is easier to track another animal than to avoid it (because an animal can move faster than its scent diffuses, so the scent trail is left behind). Perhaps chasing did not evolve because the metabolic cost of movement increases linearly with speed, so a more efficient strategy is to consume food close to its source and to wait for prey there.

## Conclusions and future work

We present here an artificial life system in which animats evolved life strategies that involved searching for food, avoiding predators, and waiting for prey near food sources. The animats can sense the food diffusing from sources, and the prey or predator scent diffusing from other animats. We show that it is possible to simulate the evolution of hundreds of such animats using a simple, but still realistic model of a 2-dimensional liquid environment. In particular, we modelled diffusion using a grid (represented as a quad-tree) with the resolution that adapts dynamically to concentration of chemicals and the movement of animats. The animats move in continuous space, and we approximated continuous concentration gradients using bilinear interpolation.

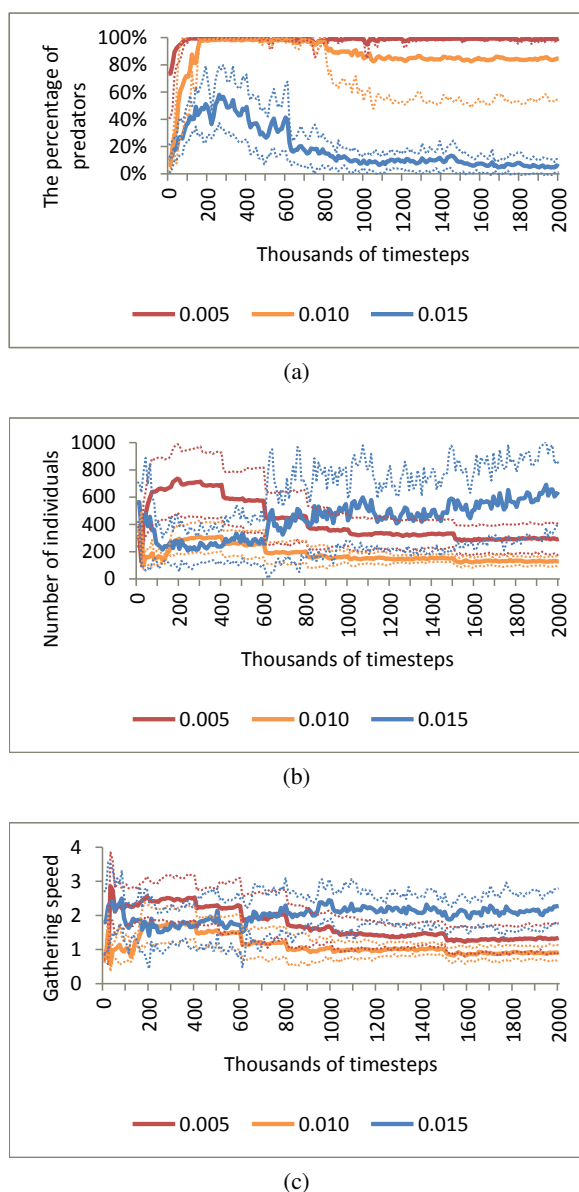

Figure 5: The percentage of predators, population size, and the amount of food stored by all the animats in the population per time step (gathering speed) for various metabolic costs of predation. Solid lines: averages over independent runs in which the populations did not die out before time step 2 000 000; dotted lines: averages  $\pm$  standard error.

The environmental conditions in our system can be adjusted to be qualitatively similar to those experienced by unicellular organisms. Some of such organisms—like the animats in our system—propel themselves using flagella and sense gradients across their one-celled bodies. Although many such organism live in 3-dimensional liquid environments, 2-dimensional environments (surfaces) also abound

in nature, and gravitation or other forces may deliver food to such surfaces in the form of food particles. The behaviour of our animats is controlled by gene regulatory networks, and the state of this network determines if an animat is a predator (this incurs higher cost) or prey. The cost of predation can be seen as the cost of producing cellular structures necessary to kill or digest the prey, and to defend the cell against other predators. The gene regulatory networks evolve in a way that is biologically realistic, without any objective fitness function or a genetic algorithm. The survival and reproduction in our system depends on animats' ability to find food and possibly prey (in the case of predators) or avoiding predators (in the case of prey). We plan to see in our future work if more complex environments (for example, obstacles, patchiness or seasonality of the food supply) or other environmental conditions will allow in our system for the evolution of other complex behavioural strategies and to the observation of general patterns in evolution (Dorin et al., 2008) in this virtual ecosystem.

## Abstract

In this paper we introduce the FARSA open-source tool that supports the accomplishment of experimental research in Embodied Cognitive Science and Adaptive Behavior. The tool provides a set of integrated libraries and a graphical interface that enable to design, to accurately simulate and to analyze individual and/or collective embodied robotic models. The modular architecture of the tool allows to progressively expand it with new software components and simplifies the implementation of custom experiments. The tool comes with a set of exemplificative experiments and with a synthetic but comprehensive documentation that should enable users to quickly master its usage.

## Introduction

The realization of the importance of embodiment and situatedness for the study of behavior and cognition led to a paradigm shift toward the so-called Embodied Cognitive Science (Clark, 1999; Pfeifer and Bongard, 2007; Shapiro, 2007). From a methodological point of view this change implies that models of behavioral and cognitive capacities should take into consideration the characteristics of the agent's nervous system, of the agent's body, of the environment and of the properties that arise from the agents/environment interactions. This in turn requires the formulation of models that are far more complex than their previous disembodied counterpart and that are not constituted simply by static descriptions but rather by processes that run in the physical world or in realistic computer simulations.

The recent development of robotic platforms that are relatively affordable and easy to use (such as the Khepera<sup>1</sup> and the Nao<sup>2</sup> robot) as well as the development of software libraries that enable the realization of realistic simulations of physical processes (such as ODE (Smith, 2004) and Newton Dynamics (Jerez and Suero, 2004)) constitute important facilitators for the design of embodied models. Despite of that,

the knowledge barrier that Embodied Cognitive Science researchers should face to build and analyze their models is still very high.

To mitigate this problem we developed FARSA, an open-source software tool that enables researchers and students to easily and effectively carry on research in Embodied Cognitive Science. FARSA combines in a single framework the following features:

- it is open-source, so it can be freely modified, used and extended by the research community;
- it is constituted by a series of integrated libraries that allow to easily design the different components of an embodied model (i.e. the agents' body and sensory-motor system, the agents' control systems, and the ecological niche in which the agents operate) and that allow to simulate accurately and efficiently the interactions between the agent and the environment;
- it comes with a rich graphical interface that facilitates the visualization and analysis of the elements forming the embodied model and of the behavioral and cognitive processes originating from the agent/environment interactions;
- it is based on a highly modular software architecture that enables a progressive expansion of the tool features and simplifies the implementation of new experiments and of new software components;
- it is multi-platform, i.e. it can be compiled and used on Linux, Windows, and Mac OS X operating systems;
- it comes with a set of exemplificative experiments and with a synthetic but comprehensive documentation that should enable users to quickly master the tool usage.

In section 2 we discuss the relation with other similar tools. In section 3 we review the main features and capabilities of the tool. In section 4 we describe the design and working principles of the software architecture. Finally in section 5, we describe the planned future extensions of the tool.

<sup>2</sup><http://www.aldebaran-robotics.com/en/>

## Related Tools

Objectives similar to those we have tried to reach with FARSA have been actively pursued during the last 20 years by academic research laboratories, small private companies, and multinational companies. Here we restrict our analysis to the most related attempts.

One of the first and most influential tool is Webots™ (Michel, 2004) a mobile robot simulator, initially developed by Olivier Michel at the Swiss Federal Institute of Technology (EPFL) in Lausanne, Switzerland, and then commercialized by a small spin-off company led by the software creator. The tool is used by about 1000 research centers and universities worldwide. Webots™ includes a robot simulator with a rich collection of predefined robotic models, a visualization tool that allows to observe the robot's behavior, a library of methods for customizing the robot and the environment, and a library of simulated sensors and actuators. A limitation of this tool is constituted by its commercial nature that introduces a cost barrier, prevents the possibility to fully inspect and customize the source code, and limits the possibilities to exploit collaborative development.

ARGOS (Pinciroli et al., 2012) is a recently developed 3D physic simulation tool targeted particularly toward swarm robotics research. It is an open source project. The usage of the tool, however, require a significant programming effort also due to the lack of an integrated graphical interface.

USARSim (Carpin et al., 2007) is also open-source simulator that was initially targeted toward urban search and rescue scenarios and later extended toward a more general use. It supports a wide range of robotics platforms (humanoids, wheeled, vehicles, etc) and has been adopted as a simulation platform by the Robotcup initiative. USARSim is an open source project which, however, is based on the Unreal Engine proprietary technology. This limits the inspection and the customization of the tool at the level of the robot implementation and impose the use of a particular proprietary language (unreal script) for the configuration of the experiments.

Gazebo (Koenig and Howard, 2004) is another open-source simulator analogous to USARSim but does not use any third party proprietary code. Another advantage of Gazebo is that it can be used in combination with Player (Gerkey et al., 2001) a tool that can be used to design the agents' controller and eventually the adapting process. The two tools are constituted by independent software programs that communicate through a dedicated network protocol. The combination of these tools constitute a powerful environment. Its use, however, requires a significant programming expertise and learning efforts.

Finally, Microsoft and Willow Garage developed two similar robotic suites: Microsoft Robotics Developer Studio

(RDS)<sup>3</sup> and Robot Operating System (ROS)<sup>4</sup>. These packages, that constitute a sort of operating system and a developmental environment for robotics applications, include device drivers, libraries, visualizers, message-passing, package management, 3D simulation tools, visual programming languages, a library of simulated robotic platforms, sensors, and actuators. The limits of these tools, for what concerns the objective addressed in this paper, is their complexity and consequently the required expertise and learning efforts. Another technical limitation is constituted by the fact that they are not multi-platform: Microsoft RDS runs only on windows while ROS runs only on Linux, limiting community collaborations.

The FARSA project aims to provide an open-source and multi-platform tool that it is easy to use and to extend and, in addition to a robotic simulation environment, provides integrated tools for designing the control systems of the robots, for analysing the robots' behaviour, and for subjecting the robots to evolutionary and/or learning processes.

## Features and Capabilities

FARSA is a re-engineered and extended version of a tool that has been developed since the 1995 by Stefano Nolfi and Onofrio Gigliotta (Nolfi, 2000; Nolfi and Gigliotta, 2010) which has been used for research and education purposes by more than 50 research laboratories and universities. It is in an open-source software tool that can be freely used and modified and a cross-platform application that runs on Linux, Windows and Mac OS X (on either 32bit or 64bit systems). The tool can be downloaded from <http://laral.istc.cnr.it/farsa>. FARSA is well documented, easy to use and comes with a series of exemplificative experiments that allow users to quickly gain a comprehension of the tool. These experiments can be used as a base for running a large spectrum of new experiments that can be set up simply by editing a configuration file.

The tool is constituted by a series of integrated software libraries providing the features described in the following sub-sections.

### The Robots/Environment Simulator

The robots/environment simulator (*worldsim*) is a library that allows to simulate the robot/s and the environment in which it/they operate. The library supports both individual robot simulation and collective experiments in which several robots are placed in the same environment. The physical and dynamical aspects of the robots and of the robots/environment interactions can be simulated accurately by using a 3D dynamics physics simulator or by using a faster but simplified kinematic engine. For what concern the dynamics simulation, FARSA relies on the Newton Game

<sup>3</sup><http://www.microsoft.com/robotics/>

<sup>4</sup><http://www.willowgarage.com/pages/software/ros-platform>

Dynamics engine (Jerez and Suero, 2004) that enables accurate and fast simulations. The underlying dynamic engine has been encapsulated so to enable the inclusion of alternative engines.

Currently, FARSA supports the following robotic platforms: the Khepera (Mondada et al., 1994), the e-Puck (Mondada et al., 2009), the marXbot (Bonani et al., 2010) (see Figure 1, bottom) and the iCub (Sandini et al., 2004) (see Figure 1, top). These robots have been designed by assembling a series of building blocks (physical elements, sensors, and motorized joints) that users can re-use to implement alternative, not yet supported, robots.

In the case of the iCub, the simulator is based on the YARP (Metta et al., 2006) middleware library (the same command used to read the robot's sensors and control the robot's motor can be used to work with the simulated or real robot). This strongly facilitates the possibility to port results from simulation to reality and the possibility to integrate into FARSA projects the software modules available from the iCub software repository<sup>5</sup>. With respect to the iCub simulator developed by Tikhonoff et al. (2008), the simulation library included in FARSA presents a series of advantages: it strictly conforms to the real kinematic joints structure of the robot, it allow to simulate multiple robots, it includes both a dynamic and kinematic engine, and it provides an enhanced visualization tool.

### The Sensor and Motor Library

FARSA also includes a library of ready-to-use sensors and motors. In some cases, sensors and motors include software routines that pre-elaborate sensory or motor information (e.g. to reduce its dimensionality) and/or integrate different kinds of sensory-motor information (as in the case of motors that set the torque to be produced by a joint motor on the basis of the current and desired position of the controlled joint).

Wheeled robots are provided with infrared, ground, traction force, linear vision, and communication sensors, among others. Moreover, they are provided with wheels, grippers, LEDs, and communication actuators.

The iCub robot is provided with proprioceptors that measure the current angular position of the robot's joints, tactile sensors, and vision sensors among others and with actuators that control all the available DOFs.

The state of the robot's sensors and motors, as well as the state of selected variables of the robot's control system, can be graphically visualized while the robot interacts with the environment (see Figure 2). This provides an useful analysis and debugging tool.

### The Controller Libraries

These libraries enable the user to design, modify and visualize the robot's control system. Currently FARSA includes

<sup>5</sup>[http://wiki.icub.org/iCub\\_documentation/](http://wiki.icub.org/iCub_documentation/)

Figure 1: Snapshots taken from the 3D robot/environment renderer of FARSA. Top: A simulated iCub robot that reaches and grasps a spherical object located over a table. Bottom: A simulated marXbot robot that navigates in a structured environment containing walls and coloured objects.

two libraries that support the design of neuro-controllers. Users willing to use other architectures or formalisms can integrate into FARSA alternative libraries (see the section “Extending FARSA”).

Evonet is an easy-to-use library that enables users to graphically design, modify and visualize the architecture of the robot’s neural controller as well as the properties of the neurons and of the connection weights (see Figure 2). The library supports logistic, leaky integrator, and threshold neurons. NFW is an alternative object-oriented library that provides a larger variety of neuron types and output functions (Gaussian, winner-take-all, ramp, periodic, etc.) and supports the use of radial basis function neural network.

Thanks to the integration between the controller and the sensory and motor libraries, the sensory and motor layer of the neural controller is automatically generated on the basis of the selected sensors and motors. Moreover, the update of the sensory neurons and the update of the actuators on the basis of the state of the motor neurons is handled automatically.

Finally, the graphic viewer of the robot’s controller (see Figure 2) also enables users to lesion and/or to manually manipulate the state of the sensors, internal, and motor neurons in order to analyze the relationship between the state of the controller and the behavior that originates from the robot/environment interaction.

## The Adaptation Libraries

These libraries enable the user to subject a robot or a population of robots to an adapting process (i.e. to a evolutionary and/or learning process during which the characteristics of the robots are varied and variations are selected so to improve the abilities of the robots to cope with a given task/environment).

The adaptation libraries that are currently available support the use of evolutionary algorithms (including steady state, truncation selection, and Pareto-front algorithms), supervised learning algorithms (i.e. back-propagation), and unsupervised learning algorithm (i.e. Hebbian learning). The evolutionary algorithms are parallelized at the level of the individual’s evaluation and can therefore run significantly faster in multi-core machines and computer clusters.

In the case of evolutionary and supervised algorithm, the variation in performance during the adaptation can be monitored and analyzed in the associated graphic renderer (see Figure 3).

## Design and Working Principles

The architecture of FARSA is based on three key ideas: the *components*, the *configuration file* and the *plugins*.

The *components* are software modules that implement a given object or process. They can be organized in a hierarchical manner. For example, a project might include an

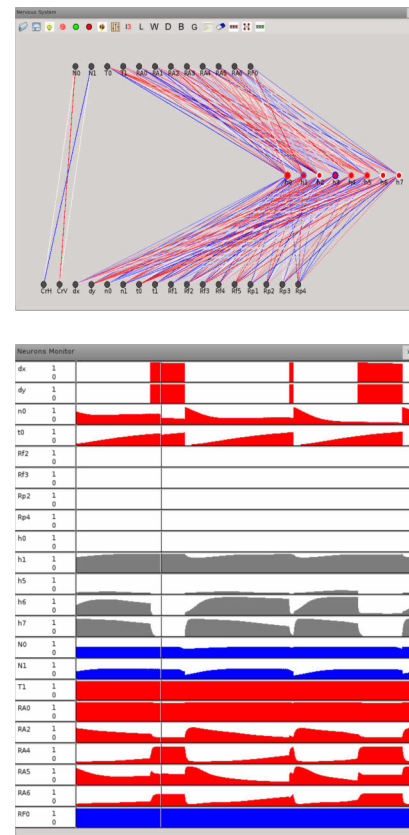

Figure 2: Top: The controller graphic widget that allows to visualize, modify, and analyze the robot’s neural architecture, the strenght of the connection weights and biases, and the properties of the neurons. Bottom: The controller monitor that displays the activation state of the sensory, internal, and motor neurons while the robot interacts with the environment.

Figure 3: The graphic widget of the adapting process. In this example, the widget is used to show the best, average and worst fitness of an evolutionary experiment through out generations.

evolutionary process component, that includes as subcomponent an experimental component, that includes as subcomponent an iCub robot component, a neural network controller component, and several sensors and motors components. The main characteristic of components is that they can be automatically instantiated and configured from the content of a *configuration file* (they have a direct relation to groups of parameters in a *configuration file*, as explained below). Components might also include associated commands (e.g. <“evolve”, “stop”, “test”> in the case of an evolutionary component), and graphical widgets that can be accessed by the FARSA main graphic interface (see next section).

The *configuration file* is a text file that specifies the components (e.g. the robotic platform, the robots’ sensors and the motors, the robots’ controllers, and eventually the robots’ adapting process) that are going to be used in a particular project and the parameters (e.g. the number of robots situated in the same environment, the number and type of objects present in the environment) that are used to configure them. The file has a hierarchical structure analogous to the hierarchical organization of components. The configuration file is a human readable text file (in .INI or .XML format) that can be edited through the Total99 graphic interface (described in the next section) or directly through a standard text editor. This enables users to configure and run experiments on remote machine (e.g. computer clusters) that do not have a graphical environment. The modular and hierarchical organization of components combined with the configuration file has several advantages:

- it allows to instantiate at runtime only the components that are needed in a particular project, thus eliminating the risk that problems affecting other components might affect the functionality of the whole project,
- it gives the possibility to re-use the same components in different projects,
- it enables a progressive expansion of the tool with the development of additional components,
- it simplifies the tool usage through the visualization of only the parameters, the commands, and the graphic widgets that are relevant for a given project.

A *plugin* contains compiled code of new components or features created by users. They might consist of subclasses of existing components (e.g. a subclass of an evolutionary experiment with a new implemented fitness function or a new subclass of the sensor class implementing a new type of sensor not available in the sensor library) or of completely new components (e.g. a behaviour-based controller tool with associated parameters, commands and graphic widgets). The plugins, which are loaded and instantiated at run time, are totally equivalent to the other native components of FARSA for what concern the functionalities and use (e.g. they can be

configured and commanded in the same manner and through the same graphic interface of the native components). Plugins provide several advantages:

- they enable users to neatly separate their new code from the main library,
- they facilitate the distribution and sharing of additional components and feature within the FARSA community,
- they enable users to get access to a number of exemplary experiments that increase over time,
- they allow authors of scientific papers to provide an easy way to replicate their work.

Overall the workflow in FARSA is as follows: the project configuration file and the required plugins are loaded, the required components are created and configured on the basis of the configuration parameters, the associated commands and graphical widgets are created and made available to the user through the graphic interface.

### The graphical interface

Total99 is the graphical interface that allows to configure experiments, to instantiate the required software components, and to use the associated commands and graphic widgets. Total99 can also operate in batch mode without graphics if required. Total99 can be used to create, view, or modify a configuration file (Figure 4). This can be done by loading or creating a configuration file (through the use of the commands available in the File menu) and by then setting the configuration components and parameters through the parameters widget (orange rectangle of Figure 4).

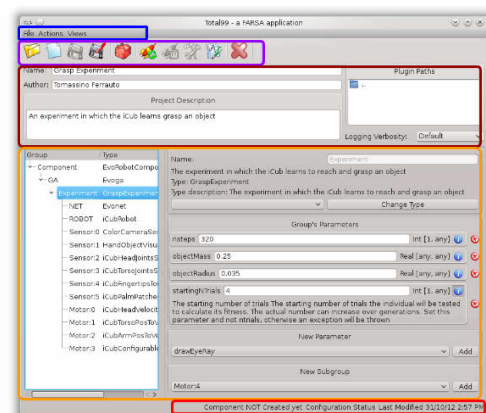

Figure 4: The Total99 graphical interface. The menu bar (blue), the toolbar (magenta), the project information bar (brown), the project parameters widget (orange), and the status bar (red) have been highlighted with coloured rectangles.

More specifically, the left part of the parameters widget is used to display the hierarchical organization of the components and the right part is used to display the parameters of the currently selected component and/or to add or remove sub-components and parameters (these can be selected from automatically generated lists that include only the parameters that belong to the current component and the sub-components that can be instantiated from the current component).

Once the configuration file has been set up, the user can run the project through the menu or the tool bar. As we mentioned above, this initiates the loading of the selected plugins, the instantiation of the software components specified in the configuration file, and the configuration of the components on the basis of the parameters specified in the configuration file. At this point, the commands associated to the components that have been instantiated and the associated graphic widgets can be executed from the Action and Views folders of the menu bar.

### Extending FARSa

FARSa can be extended by implementing additional software components. The integration of the new components into FARSa, that enables the possibility to use, execute, and configure them as native components, requires to fulfill the following three requirements.

The first requirement is that the class of the new component should be defined as a sub-class of an existing component or of a virtual empty component.

The second requirement is that the new class should include a `describe()`, `save()`, and `configure()`<sup>6</sup> functions that are used respectively for declaring the properties of the configuration parameters, saving the current value of the parameters on the configuration file when requested, and configuring the object on the basis of the parameters. For all these operations, FARSa provides helper functions in order to simplify and to minimize the effort of writing them.

The third requirement is that the new component has to be registered with the `registerClass()` function specifying the component type name.

In the case of components that also include new commands and/or new graphic widgets (that should be made available from the Total99 graphic interface), the user should also declare the new commands and/or widgets by implementing the `fillActionsMenus()`, `getViewers()`, and `addAdditionalMenus()` functions.

More detailed information can be found in the on-line documentation.

### Future Plans

The first stable version of FARSa has been just released online. During the next few months we plan to refine and

<sup>6</sup>Instead of implementing the `configure()` function, it is possible to implement a special constructor of the class

extend the documentation and the library of the exemplificative experiments. Then we plan to keep extending the tool, to promote the development of a community of users and developers, and to develop multimedia materials that can enrich the educational and training potential of the tool.

### Planned Extensions

Currently planned extensions include: (i) additional controller and adaptive software components that will enable the direct use of other formalisms and training algorithms (e.g. self-organizing maps, fuzzy networks, reinforcement learning) as well as the combined use of different techniques (e.g. unsupervised and supervised learning algorithms), (ii) additional readily available robotic platforms, and (iii) the possibility of using a simple script language as an alternative to C++ to implement new types of experiments.

### FARSa Community

The full open-source nature of FARSa and its modular architecture constitute two important prerequisites for the development of a wide community of users and developers that can profit from the tools and can contribute to its further extension. To enable the formation of such community we plan to widely disseminate the tool and to create web-based facilities that can be used to store users' knowledge and plugins.

### Educational Use of FARSa

The simplicity of use potentially enables FARSa to also become an excellent educational tool. To promote this use we plan to develop and promote the collaborative development of tutorials and training material targeted toward undergraduate and graduate courses in Embodied Cognitive Sciences and Autonomous Robotics. Finally we plan to develop examples of serious games (Marsh, 2011; Miglino et al., 2008, 2007) that could be used to disseminate key concepts also to the general public, within Science Museums and Festivals, and to students of the primary and secondary schools.

### Conclusion

FARSa is an easy to use open-source tool that can enable students and researchers with a limited technical expertise to start building and experimenting with embodied cognitive science models and enables experienced researchers to use a powerful tool that can be easily configured and extended. Moreover, it provides an unique set of integrated tools that strongly facilitate the design of neuro-robotics and adaptive robots. The current version of the tool has been extensively used and tested to carry on frontier research in adaptive robotics (Massera et al., 2007; Gigliotta and Nolfi, 2007; Tuci et al., 2009; Massera et al., 2010; Tuci et al., 2011; Savastano and Nolfi, 2012; Leugger and Nolfi, 2012) in our lab. We hope the public and well-documented version of the tool that we just released will attract a wide interest

and will permit the establishment of a wide community of users and developers.

### Acknowledgments

This research has been supported by CNR, in part under the European Science Foundation project Hierarchical Heterogeneous SWARM (H2Swarm). The authors thank Piero Savastano, Fabrizio Papi, and Tobias Leugger who contributed to the development of the tool.

## Abstract

This paper describes insect type micro robots controlled by a CMOS IC of hardware neural networks. The micro robot is fabricated by the micro electro mechanical systems (MEMS) technology using a silicon wafer, and the actuator is composed of artificial muscle wires on the basis of shape memory alloy. Insect-like walking is achieved by link mechanisms that transform the actuator's rotational motion to locomotive motion. The CMOS IC generates the driving waveform of the micro robot and realizes insect-like walking. The hardware neural networks are built as cell body models and inhibitory synaptic models. The output signal ports of the hardware neural networks are connected to the artificial-muscle-wire-driving circuit. This robot system does not require specialized software programs and A/D converters. The developed neural networks are composed of self-functioning, interconnected plural unit neurons. For proper driving, each neuron in the developed neural network control must be synchronized, as occurs in the neural networks of living organisms. In this study, the motion of the MEMS micro robot is controlled by non-synchronization and anti-phase synchronization driving waveforms. When the non-synchronization driving waveform is input, the micro robot ceases walking motion, but resumes walking upon receipt of the anti-phase synchronization driving waveform. The sideways, endways, and height dimensions of the fabricated micro robot are 4.0 mm, 2.7 mm and 2.5 mm, respectively. The obtained locomotion speed is 26.4 mm/min and the step width is 0.88 mm.

## Introduction

Insect-like micro robots have been increasingly applied in medicine and other fields that require precise manipulation (Shibata et al., 1997; Takeda, 2001; Habib et al., 2007, 2011; Baisch et al., 2010; Yan et al., 2007). However, to date, very few insect robots are operational at the level of living organisms. Developmental obstacles include the miniaturization of the mechanism, small energy requirements for ensuring long lifetime, and realizing the flexibility of living organisms.

In conventional robot mechanisms, the dominant actuator is an electromagnetic motor, and robotic components are manufactured by mechanical machining. However, very small robots cannot be fabricated by conventional technologies. To overcome this limitation, researchers have developed the micro electro mechanical systems (MEMS) technology on the

basis of the IC production process (Donald et al., 2006; Edqvist et al., 2009). The miniature actuators reported to date include electrostatic actuators (Tang et al., 1989; Sniegowski et al., 1996), electromagnetic actuators (Asada et al., 1994), piezoelectric actuators (Suzuki et al., 1999), and shape memory alloy (SMA) actuators (Surbled et al., 2001). However, the movement of micro robots built with these actuators is impeded on uneven surfaces by small gaps or dust particles. Therefore, micro robots that can walk on an uneven surface are highly sought.

Conventional robot control is implemented by digital systems based on microprocessors and software programs. While the pre-programmed digital system exerts adequate control in the specified environment, it may not respond appropriately to unpredictable events. As a means of realizing flexible control, artificial neural networks have attracted considerable attention (Nakada et al., 2003; Delcpyn, 1980). For example, an organism such as an insect realizes walking motion by combining simple neural networks. Moreover, living organisms are flexible and respond sensitively to accidental events. For these reasons, artificial neural network control is a preferable choice in micro robot design.

Neural networks have mostly been investigated by software approaches based on mathematical calculations (Tsumoto et al., 2003, 2006; Tsuji et al., 2007; Hodgkin et al., 1952; FitzHugh, 1961). However, using this approach, even simple neural networks consume vast physical and temporal computer resources. Therefore, several researchers have implemented neural networks in hardware (Endo et al., 1978; Kitajima et al., 2001; Yamauchi et al., 1999, 2003; Nagumo et al., 1962; Maeda, 2008). Hardware networks can process nonlinear operations continuously at high speed. Moreover, because the circuit can be embodied in an integrated circuit (IC) (Lewis et al., 2000), extreme size reduction is expected even for large circuits.

The previous micro robot system reported by the authors (Suematsu et al., 2009; Saito et al., 2010; Okazaki et al., 2011) possessed two legs controlled by the MEMS technology and a plastic body. The actuator was fabricated by SMA. The micro robot was controlled by pulse-type hardware networks (P-HNNs), functioning similarly to the central pattern generator of living organisms. The P-HNN was composed of discrete components. In the next step of the project, the six-legged structure and walking motion of the insect were developed. The rotational actuator used SMA-based artificial

muscle wires, and walking motion was realized by link mechanisms. Motion was controlled by a hardware neural network circuit connected to the actuator. Moreover, the micro robot dimensions were reduced to 4.0 mm, 2.7 mm, 2.5mm in the sideways, endways and height directions, respectively (Uchikoba et al., 2012). In this study, the robot was again controlled by discrete P-HNN circuits.

Recently, we built hardware neural networks into CMOS IC. The IC was connected to the insect-type MEMS micro robot, and its performance was evaluated. In this paper, we explain the mechanism and system of the micro robot and P-HNN IC, and discuss the control characteristics of the P-HNN IC. The driving waveform is provided by synchronization of several hardware neural networks.

## System of Micro Robot

### CMOS IC Controlled MEMS Micro Robot

In future applications, the developed micro robot will observe and possibly lead swarms of similar micro robots. Therefore, the robot should resemble a live insect as much as possible. For this purpose, we consider hexapod walking motion as a primary objective. Figure 1 shows the mechanism of the designed micro robot.

Figure 1: Mechanism of the Designed Micro Robot

The robot is fitted with six legs on either side. Three of the legs are connected by the link mechanism, while the central leg is held on the rotational actuator built into the body parts. The rotor of the actuator is suspended by artificial muscle wires extending in four directions. The artificial muscle wires, composed of SMA, shrink when heated above the transition temperature of the alloy, and revert to their original length by cooling below the transition temperature. The temperature is raised by flowing an electrical current directly into the wire. The wire is coiled inside the actuator to enable a larger displacement than is possible with a linear wire. The specifications of the artificial muscle wire are shown in Table 1 (<http://www.toki.co.jp>).

Coil diameter (mm)	0.2
Wire diameter (mm)	0.05
Drive current (mA)	50–120
Resistance ( $\Omega\text{m}^{-1}$ )	3600
Force (gf)	3–5
Displacement (%)	50

Table 1: Specifications of Artificial Muscle Wire

Rotational motion is realized by shrinking the artificial muscle wires in rotational order. A schematic of the actuator's rotational motion is shown in Figure 2. As wire A shrinks under heating, the rotor is pulled toward the A side. In the next step, wire A is extended by cooling, and wire B is shrunk, dragging the rotor toward the B side. The heating and cooling processes are repeated for wires C and D. These activities induce a clockwise rotation of the rotor.

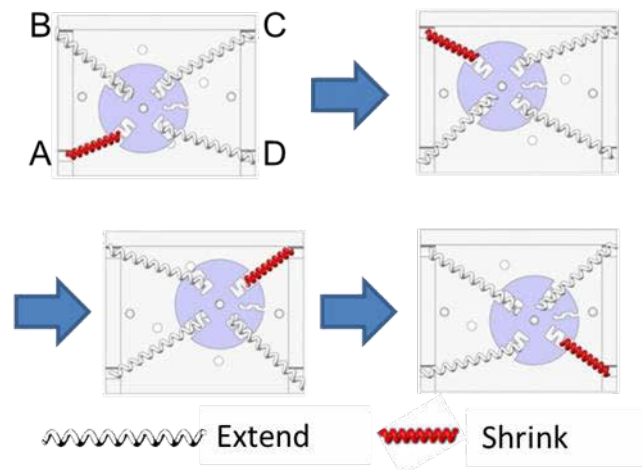

Figure 2: Schematic of Clockwise Rotational Motion of the Actuator

The driving waveform of the neural networks for generating hexapod walking motion is shown in Figure 3. The walking motion is generated by four pulses. The input voltage and pulse width are 3 V and 0.5 s, respectively.

The central leg is connected to the rotor shaft. The front and rear legs float, while the central leg touches the ground surface. Governed by the rotational motion of the actuator, the middle leg kicks the ground, propelling the micro robot body forward. As the middle leg rises, the front and rear legs touch the ground surface. The outer and central legs are out of phase by 180°. During these motions, the touched points always form a triangle, and stable walking motion, mimicking that of an insect, is realized. Moreover, backward locomotion is generated by reversing the actuator motion. The forward and backward motions are controlled by the electrical current pulses shown in Figure 3 (a) and 3 (b), respectively.

Figure 3: Schematic of Driving Waveform: (a) Clockwise Pulse (b) Reverse Rotation Pulse

### Structure of Micro Robot

The fabricated micro robot comprises the body parts, the rotational actuator, and the legs. The body, legs, and actuator rotor are made from single crystal silicon wafers fabricated by the MEMS technology. The four frames of the body structure are assembled by jutting the parts into the grooves. For this purpose, four pieces of artificial muscle wires are connected to the rotor section of the rotational actuator, which is modified by zigzag slits. An electrical ground line is led from the rotor. The other end of the artificial muscle wire is connected to the frame. Figure 4 shows a schematic of the micro robot body and the actuator part, while the shape and dimensions of the rotor part are shown in Figure 5.

Figure 4: Schematic of Micro Robot Body and Actuator

Figure 5: Shape and Dimensions of Rotor Part

The three leg parts are connected by the link mechanism. The front and rear legs move in the counter-direction relative to the center leg. To ensure that the robot moves parallel to the ground, the central leg is made shorter than the other legs. Figure 6 shows the link mechanism of the legs. The central legs are connected to the center of the rotor by a tungsten carbide shaft, while the outer legs are held by shafts attached to the body frame.

Figure 6: Link Mechanism of Legs

The silicon part was fabricated by MEMS photolithography. After washing the silicon wafer, aluminum was deposited by physical vapor deposition, followed by coating with a photoresist. The aluminum film was approximately  $0.1 \mu\text{m}$  thick. The designed pattern was exposed to the resist film, and developed by soaking in the developer. The aluminum film on the specimen was then etched chemically, leaving an imprint of the designed pattern. The washed and dried specimen was dry-etched by high-aspect-ratio induced coupled plasma etching combined with a Bosch process (Bhardwaji et al., 1995). The rotor part was obtained after removing the aluminum film and washing. The other robot parts were obtained by repeating this process on both surfaces of the wafer. Hand assembly of the fabricated parts yielded the micro robot.

### Pulse-Type Hardware Neural Networks

The P-HNN was built from the cell body and synaptic model circuits. These circuits reproduce the functions of biological neurons.

The cell body model circuit is configured as a voltage control negative resistance circuit, an equivalent inductance circuit, membrane capacitor  $C_M$ , and leak resistor  $M_{C4}$ . The cell body model circuit is characterized by a firing threshold, refractory period, and a continuous pulse waveform, similar to the characteristics of biological neurons. Figure 7 is a diagram of the cell body model circuit, powered by source  $V_A$ .

Figure 7: Diagram of the Cell Body Model Circuit

The synaptic model circuit comprises the excitatory and inhibitory synaptic model circuits, which differ only in the direction of their current. The synaptic model circuit has spatio-temporal summation characteristics mimicking those of biological synapses. That is, the synaptic model circuit sums the output pulses of the cell body model circuit. A diagram of the synaptic model circuit is provided in Figure 8. This circuit is powered by source  $V_{DD}$ . The synaptic weight (connection strength between the cell body models) is adjustable by changing the ration of the channel length  $L$  and the channel width  $W$  in the gate of  $M_{IS1}$  in Figure 8 (b). For example,  $i_{ISout}$  is increased by increasing the  $W/L$  of  $M_{IS1}$ .

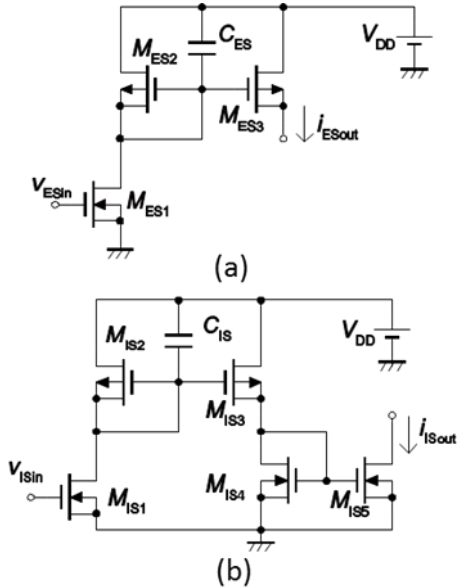

Figure 8: Diagram of the Synaptic Model Circuit: (a) Excitatory Synaptic Model Circuit (b) Inhibitory Synaptic Model Circuit

The P-HNNs are synchronized by the excitatory and inhibitory synaptic model circuits. Excitatory and inhibitory mutual coupling generates in-phase and anti-phase synchronization, respectively. During walking, we consider that the neural networks of the micro robot might consist solely of inhibitory synaptic models and anti-phase synchronization. If the excitatory synaptic model can be removed without loss of functionality, the number of elements in the model can be reduced. The P-HNN connections are schematized in Figure 9.

Figure 9: Connection Diagram of P-HNN

The four cell body models are mutually coupled by 12 inhibitory synaptic models. Four output ports, extracted from the P-HNN, are connected to the actuator of the MEMS micro robot. In addition, the trigger pulse input ports are extracted to P-HNNs. By accepting different input timing of the external trigger pulse, the P-HNN can alter the sequence of the output waveform.

### CMOS IC

Figure 10 displays the layout pattern of the P-HNN. The process line is a double-metal single-poly CMOS 0.35  $\mu\text{m}$  rule. The area of the IC chip is 1.93 mm square. Because capacitors  $C_G$  and  $C_M$  are too large to position on the CMOS IC chip, they are externally connected to the chip; this arrangement also enables straightforward dynamic frequency adjustment. Figure 11 shows a diagram of the artificial muscle wire driving circuit that generates the walking motion of the MEMS micro robot.

Figure 10: Layout Pattern of P-HNN

Figure 11: Artificial Muscle Wire Driving Circuit

## Results and Discussion

A photograph of the fabricated micro robot is shown in Figure 12. The sideways, endways, and height dimensions of the micro robot are 4.0 mm, 2.7 mm, and 2.5 mm, respectively. The dimensional error of the actuator component was measured by an optical con-focal microscope, and was found to be always within  $\pm 3 \mu\text{m}$ . Moreover, the leg and link parts were connected with adequate clearance fit (measured as 20–30  $\mu\text{m}$ ).

Figure 12: Photograph of the Fabricated MEMS Micro Robot

Figure 13 compares the discrete circuit board of the artificial neural networks with the packaged IC. This figure shows that the packaged IC was miniaturized to 3.5% of the discrete circuit area, while the bare die realized an area reduction to 0.05%. Thus, considerable size reduction may be achieved by the IC construction.

Figure 13: Size Comparison between the Discrete Circuit and the Packaged IC Discrete Circuit: 10 cm  $\times$  8 cm, Packaged IC: 14 mm  $\times$  20 mm, Bare Die IC: 1.93 mm  $\times$  1.93 mm

Figure 14 shows the output waveform of the IC chip when  $V_{DD} = 5 \text{ V}$ . At this voltage level, the inhibitory synaptic circuit is turned on. In other words, the inhibitory synaptic model circuit is connected, generating an output waveform that inhibits the other cell body model circuits. In response, the cell

body model circuit comprising  $I_1$ ,  $I_2$ ,  $I_3$ , and  $I_4$  outputs an anti-phase synchronization pattern. Since P-HNNs can generate driving waveforms such as those shown in Figure 3, we have demonstrated that the fabricated IC chip generates correct walking motion of the silicon micro robot.

Figure 14: Output Waveform of the IC Chip

Figure 15 illustrates the walking motion of the MEMS micro robot. The driving waveform that moves the robot is output by the P-HNN. The rotary actuator is then activated and the link mechanism is converted to a walking motion. The locomotion speed is 26.4 mm/min with a step width of 0.88 mm.

Figure 15: Walking Motion of MEMS Micro Robot

Figure 16: Output Waveform of IC (Non-Synchronization Mode)

Figure 17: Output Waveform of IC (Anti-Phase Synchronization Mode)

The motion of the MEMS micro robot was examined under non-synchronization and anti-phase synchronization P-HNN driving waveforms, displayed in Figs. 16 and 17, respectively. In Figure 16, four waveforms are randomly generated, while in Figure 17, they are alternately generated. In the former case, the actuator of the micro robot did not perform rotational motion, hence the robot did not achieve walking function. By contrast, when the anti-phase synchronization driving waveform was connected to the micro robot, walking motion was initiated (Figure 18). To easily visualize the leg movements, these motional comparisons were conducted on a larger micro robot than the fabricated one. The width, length, and height of this micro robot were 8.1 mm, 8.9 mm, and 9.0 mm, respectively. Each figure was observed at 0.5 s intervals. The locomotion speed of this micro robot was 96.0 mm/min with a step width of 4.0 mm. In this test, the MEMS micro robot was controlled by the CMOS IC of hardware neural

networks, whose synchronization phenomena mimicked those of brain networks.

Figure 18: Motion Response of MEMS Micro Robot to an Anti-Phase Synchronization Driving Waveform

## Conclusion

This paper proposes an insect-type MEMS micro robot controlled by CMOS IC of hardware neural networks. The micro robot contains a rotational actuator using SMA-based artificial muscle wires and possesses the hexapod structure of an insect. The dimensions of the micro robot are 4.0 mm (sideways), 2.7 mm (endways), and 2.5 mm (height).

The micro robot walks when supplied with a synchronized output driving waveform generated by the IC chip of pulse-type hardware neural networks. Thus, as in living organisms, walking motion is realized by the synchronization of artificial neural networks. Moreover, the movement of the micro robot can be controlled by pulse-type hardware neural networks. The locomotion speed is 26.4 mm/min and the step width is 0.88 mm.

In the future, other motions exhibited by living organisms will be incorporated into the insect-type MEMS micro robot, by integrating functional elements such as sensors onto a single chip. When the sensor has been integrated, the walking motion systems will form a closed loop, enabling more lifelike behavior of the micro robot. Such micro robots are not only useful in medical fields but will also assist biologists in understanding the movements of living organisms. Moreover, since the all-in-one package installed in the micro robot requires a built-in battery, the micro robot may be used to investigate electromagnetic induction-type wireless power transfer or solar cells.

# Open-Ended Evolution of a Circadian Rhythm

Tiago Baptista and Ernesto Costa

CISUC, University of Coimbra, Coimbra, Portugal  
baptista@dei.uc.pt

## Abstract

Most biological systems have some sort of adaptation to our planet's cycle of day and night. This adaptation is a current subject of scientific research, and serves as inspiration to develop a multi-agent simulation to investigate the evolution of complexity in an open-ended evolutionary framework. In a previous work, we created a simulated world where artificial organisms evolve to synchronize with a daily cycle of light and darkness. A multi-agent, artificial life framework was used to implement these simulations. In this paper, we further develop that world, by adding caves to the environment. When in these caves, the agents will perceive a low level of light, as if it were night. This adds an extra layer of complexity to the desired behavior of the agents, as now they need to distinguish "night" from "cave". Using the same agent structure, and the same open-ended evolution framework, we show that the agents evolve to adapt to this new environment. We also show how the agents adapt to the environment with caves, by analyzing their brains.

## Introduction

The study of circadian clocks and similar synchronization phenomena in biological systems is a current subject of scientific research (Rand et al., 2006; Strogatz, 2004). Despite having been extensively studied, these phenomena still have much to be investigated. Our goal, however, is not to learn more about this biological process, but to use it as an inspiration to study the emergence of complex behaviors in an open-ended evolution scenario. To that end, we implement a simulation where the environment has a day and night cycle, and analyze the evolution of the agents' behavior, and their adaptation to this cycle.

In a previous paper, the authors presented some experiments done with such a scenario (Baptista and Costa, 2008), and showed that the agents do develop behaviors adapted to the daily cycle. In an effort to create a more challenging environment, we now further developed that world by adding caves. When an agent enters a cave, the light level will be the same as if it were night time. This will force the agents to evolve behaviors capable of distinguishing the two different low light conditions, adding extra complexity to the requirements for survival.

Some previous work has been done with similar simulation scenarios, either by evolving neural networks (Mirolli and Parisi, 2003), or virtual CPU organisms in Avida (Beckmann et al., 2007). Our scenario can be mostly compared to that of (Mirolli and Parisi, 2003), as they also have an environment with varying light level and caves. However, they use a standard genetic algorithm to evolve the agents, whereas we use an open-ended evolution framework.

Although an established definition of open-ended evolution hasn't yet surfaced, most authors consider that one of the major requirements is the absence of an explicit fitness function. In other words, to have open-ended evolution, a system should be based on Natural Selection rather than Artificial Selection (Channon, 2000).

The simulations described in this paper were implemented using the BitBang framework. One of the purposes of these simulations is to serve as a proof of concept for the model developed for the framework. Implementing a modern autonomous agent model (Russell and Norvig, 2002), this framework has roots in Artificial Life systems and Complexity Science. The simulated world is composed of entities. These can either be inanimate objects which we designate as *things*, or entities that have reasoning capabilities and power to perceive and affect the world—the *agents*. Both have traits that characterize them, such as color, size, or energy—the *features*. The agents communicate with, and change the environment using *perceptions* and *actions*, taking decisions using the *brain*. In this model, there is no definition of a simulation step, as we won't have any type of centralized control. As such, the simulation is asynchronous. The agents will independently perceive, decide, and act. Moreover, there is no evolutionary mechanism included in the definition of the model, since evolution is implemented as an action. That is accomplished by giving the agents the capability of reproduction. Again, there is no central control bound to the process of reproduction. The agents choose when to reproduce and with what other agent to reproduce with. In addition, there is no explicit fitness function. The agents die due to lack of resources, predators, age, or any other mechanism implemented in the world. Thus, in this

model we have open ended evolution. To have a more in-depth view of the conceptual model and architecture of Bit-Bang, refer to (Baptista et al., 2006).

In the next section we will describe the simulation world developed, detailing the agents, things, brain architecture, evolutionary process, and environmental settings. We will then present the experimental results and end with some conclusions.

## The DayNight World

In this section we will set out all the implementation details and architecture of the simulations. As mentioned above, these simulations were implemented using the Bit-Bang framework, and therefore we will present the architecture according to the framework's specifications. We begin by describing the simulation environment, then detail the agents' architecture (features, perceptions, actions, and brain). Next, we will present the two types of things defined in this world, and finally we present the architecture of brain used in these experiments.

### The Environment

Our world is a 3D world where agents and resources are placed (see figure 1). The terrain is a square. This area restricts the placement of agents, caves, and resources, but does not restrict the movement of the agents. The world is infinite, i.e., an agent can move past the boundaries of the populated terrain. At startup, the field is populated with a configured amount of randomly placed food items. These are periodically replenished so that the total food count is maintained. The number of resources available is configurable to be able to fine tune the system so as to allow agents to survive but also provide enough evolutionary pressure.

Figure 1: Screenshot of a running simulation. We can see the agents (turtles), the edible resources (small red cubes), and the caves (large grey cubes).

On initialization, the world is populated with randomly placed, and randomly generated agents. At this time, it is highly probable that the agents will not execute the reproduction action, either by not choosing it, or because they

don't have enough energy to reproduce. To keep the population alive, whenever the number of agents in the world falls below a given threshold, new agents are created. If there are live agents in the environment, one will be picked for reproduction, otherwise a new random agent is created. Note that, as stated before, there is no explicit fitness function, so the agent chosen for reproduction will be randomly selected from the population.

To differentiate the day from the night, the environment has a light level that oscillates between a configurable maximum and minimum. For each day the maximum light level is randomly calculated as the overall maximum minus a random value between zero and the delta. The same applies for the day's minimum. For example, if the maximum light level is 100, the minimum light level is 0, and the delta is 10, each day's maximum light level will be a random value between 90 and 100, and each day's minimum light level will be a random value between 0 and 10. Additionally, the light level does not rise or fall abruptly, but rather changes linearly during a specified time interval, simulating dusk and dawn. To better illustrate, in figure 2 this variation of the light level can be observed. The duration of one day, can be configured, and remains constant for the duration of the experiment.

Figure 2: Example of the variation of the light level over the course of five days. In this example, the maximum light level is 100, the minimum is 0, and the delta is 10.

The total simulation time for these experiments was divided into two equal parts. For the first part of the simulation, the agents live in an environment that only has food items. Then, we randomly place in the environment a number of caves, and continue the simulation in this new environment. When an agent enters a cave, the light level it perceives will be the same as if it were night, creating a new challenge for our agents. By the time the caves are created, the agents will have evolved a behavior adapted to the light level, sleeping when the light is low, and being active when its high. However, when an agent enters a cave, it will not be able to distinguish if the low light level means "night" or "cave". If it simply goes to sleep whenever the light level is low, it will never wake up again, as the light level in the cave will never rise. Our agents will now have to adapt their behavior to this new environment.

## The Agents

In this simulation only one type (species) of agent exists, and has the following architecture:

- **Features:** energy, metabolic rate, and birth date.
- **Perceptions:** energy, resource location, reach resource, light level.
- **Actions:** move front, turn left, turn right, sleep, eat, reproduce.
- **Brain:** rule list (see section ).

We will now describe each one of these components.

### Features

**Energy** This feature represents the current energy level of the agent. When this feature reaches zero, the agent dies. The feature is initialized with a predetermined value at agent birth. For these simulations, the agents are initialized with 10 energy units.

**Metabolic Rate** The metabolic rate is the amount of energy the agent consumes per time unit. This rate is initialized to its configured base value, and changes as the agent moves or sleeps. The increase or decrease amounts for move and sleep are configurable.

**Birth Date** This feature is set to the current time at birth and remains constant. It is used to calculate the agent's age. When the agent reaches a given age, it dies. This procedure allows the evolution to continue past the moment when the agents have developed good navigation and eating capabilities, whilst maintaining an asynchronous and open-ended simulation. The maximum age of the agents is configurable.

### Perceptions

**Energy** This is a self-referencing perception on the agent's current energy level. This perception is tied to the corresponding feature. This is a numerical perception, and the range of values can be configured.

**Resource Location** This is the agent's main perception of vision, representing the position of the nearest resource, relative to the agent's position and orientation. The agent's vision is implemented as a 3D cone in front of the agent. The vision cone is configured with a given range and angle, representing its height and aperture. This is a numerical perception with possible values 0, 1, 2, and 3. The value 0 means no resource is visible. The value 1 means there is a resource to the left. The value 2 means there is a resource directly in front of the agent. The value 3 means there is a resource to

the right. This perception is influenced by the light level of the environment. As the light level drops, so does the range of vision for the agent, using the following equation:

$$V(t) = V_0 \frac{L(t)}{L_0}, \quad (1)$$

where  $V(t)$  is the vision range at time  $t$ ,  $V_0$  is the configured vision range of the agents,  $L(t)$  is the light level at time  $t$ , and  $L_0$  is the configured maximum light level.

**Reach Resource** This is a boolean perception that evaluates to true whenever the agent has a resource within its reach. The distance the agent can reach is configurable.

**Light Level** This perception gives the agent the power of sensing the brightness of the environment. This can also be considered a perception of vision. The value of the perception is numeric and, at each time, is evaluated to the environment's current light level if the agent is outside. When in a cave, the perception evaluates to the minimum light level whether it is night or day.

### Actions

**Movement** We define three actions for movement. One to walk forward, one to turn left, and one to turn right. These actions have a tie to the metabolic rate feature in such a way that whenever the agent is moving, the metabolic rate increases.

**Eat** This action enables the agent to eat a resource within its range. If no resource is in range when the action is executed, nothing happens. This action will add a configured amount of energy to the agent's energy feature.

**Sleep** The agent can use this action to sleep. In this simulation, when an agent is sleeping, it will stand still and its metabolic rate will decrease, falling below the base metabolic rate and thus allowing the agent to conserve energy. As for the rest of the actions, it gets executed whenever the agent chooses to do so.

**Reproduce** This action allows the agent to reproduce itself. The reproduction implemented is asexual. When the action is executed, a new agent is created and placed in the world. The new agent will be given a brain that is a mutated version of its parent's brain. Note that, as each mutation operator has a given probability of being applied, the child's brain can be a perfect clone of its parent's brain. The action will also transfer energy from the parent to the offspring. The amount of energy consumed in the action is the sum of the initial energy for the new agent and a configurable fixed cost. It's important to have a cost of reproduction higher than

the initial energy of an agent, so as to provide evolutionary pressure.

**Brain** The agents' brain used in these experiments is a rule list. The architecture of this system is explained in section . On initial creation of an agent, the brain is randomly initialized. This initialization conforms to some configurable parameters: the maximum number of rules, the minimum number of rules, and the maximum number of conditions per rule. Other configured values are the mutation probabilities used in the reproduction action.

### The Things

Two types of things have been defined for this world: the resources that the agents eat to acquire energy, and the caves. No features are associated with them. A configurable parameter defines the amount of energy each resource provides. Although the caves are also represented as things, they are not visible to the agents, or else, it would be easier for them to distinguish "night" and "cave".

### The RuleList Brain

The Rule List brain is composed of an ordered list of rules. The reasoning process is straightforward. The rules are evaluated in order, and the first one whose conditions are all true, is selected. Each rule is composed of a conjunction of conditions and an action. The structure of a rule is shown in listing 1. Next, to illustrate, in listing 2 we provide an example of a rule.

#### Listing 1 Syntax of a rule in the RuleList brain.

```
<rule> ::= IF <cond-list> THEN <action>
<cond-list> ::= <condition>
<cond-list> ::= <condition> AND
<cond-list>
<condition> ::= <percept> <operator>
<percept>
<condition> ::= <percept> <operator>
```

#### Listing 2 Example of a rule.

```
IF energy < 10 AND reach_resource TRUE
THEN eat
```

The use of this brain architecture has the added benefit of readability. It is easy to understand the reasoning process by looking at the agent's rule list. This feature will permit a better analysis of the results.

To be able to evolve this brain architecture we need to define its equivalent to the genome, and the operators that modify it on reproduction. The brain's genome is the rule list itself, no translation is applied. To alter it we defined only mutation operators. These operators are show in table 1.

Table 1: Mutation operators of the RuleList brain.

Operator	Description
<b>Mutate List</b>	This operator iterates through the rule list, and replaces a rule with a new random one.
<b>Mutate Rules</b>	This is the lowest level operator. It drills down to the perceptions on the conditions and mutates both the perceptions and their operators. It also mutates the action of the rules.
<b>Mutate Order</b>	This operator iterates through the rule list and moves a rule to the top of the list.
<b>Mutate Order 2</b>	This operator iterates through the rule list and moves a rule one position towards the top.

Not all of the mutation operators must be used. The programmer decides which of them to use for a particular experiment. In the case of the experiment described in this paper, the operators used were the *Mutate Order*, *Mutate Rules*, and *Mutate List*.

## Results

In this section we will expose and analyze the results of the experiments. But first we give an overview of the main configuration values used for the simulations. Most of the configuration values presented are the result of previous experimentation done on (Baptista and Costa, 2008).

The terrain is a square with sides of 1000 units. This field is populated initially with 20 agents, and that is also the minimum number of agents. These initial agents are generated with a brain composed of a random set of rules. The agents' brains are initialized with between 15 and 20 rules, having each up to 2 conditions. The initial and minimum number of food items is 200. One day lasts for 100 time units and the transitions from day to night, and vice versa, last 10 time units. The light level has a maximum of 100 and a minimum of 0, with a delta of 10. That means that for a given day the actual maximum light level will be between 100 and 90, and the minimum level between 0 and 10. Each agent is created with a vision range of 200 units and a vision angle of 60°. The agents reach is 20 units. Agents are initialized with energy 10 and consume a base metabolic rate of 0.1 energy units for each time unit. The metabolic rate increases by 0.01 when the agent is moving and drops by 0.03 when sleeping. The maximum age of the agents is 500 time units. The cost of reproduction is 2 energy units, plus the energy initialization for the child agent. Each food item gives an agent 3 energy units. The mutation probabilities are 0.01 for every operator. These experiments were run with a time limit of 200,000 time units. The caves were placed in the

environment at time 100,000.

Regarding the configuration parameters for the caves, as they represent the main addition to these experiments, we ran simulations with different configuration values. All caves have a side of 50. The field is populated with either 50, 20, or 10 caves.

For the experiments presented here, we ran 30 independent simulations for each configuration of the parameters. As is the case in (Baptista and Costa, 2008), from those 30 simulations, there are some where the agents will not be successful in evolving good foraging behavior, and thus will not be able to further evolve reproduction or synchronization to the day cycle. These experiments were not taken into account for some of the results shown in this section. Whenever that is the case, it will be stated.

Next, we will present and analyze the data of typical runs from the simulations. From all the simulations and runs analyzed, we found mainly two different types of plot (see figure 3 and figure 4). These represent the majority of results from the runs (except for those that are unsuccessful). Both the figures are taken from runs with the same parameter configuration (50 caves).

Figure 3: Plot of the evolution of the total number of agents in the population, average gathered energy, percentage of agents in sync with the day cycle, and percentage of agents that found caves, over the course of one simulation run (number of caves is 50).

The first type of plot, shown in figure 3, is what we expected to find in this experiment. Here, the population collapses and loses synchronization when the caves are inserted into the environment. Examining this plot, we can clearly see the agents are successful in evolving food gathering, reproduction, and synchronization in the first environment (up to time 100,000). Then, when the environment changes, most of the population dies and never recovers food gathering capabilities.

In fact, this data is consistent with what is presented in (Mirolli and Parisi, 2003). In that paper, the authors

show that, when the agents only have an input of the light level, they are not able to differentiate the “caves” from the “night”. They provide a possible solution to the problem, by incorporating in the structure of the brain, a clock source. However, in our simulations, we found that on a significant number of runs (see table 2) the agents do recover.

In figure 4 we show an example of a typical run where the agents recover in the second environment. In the first environment, we find a plot similar to that of figure 3. The agents develop good food gathering capabilities, reproduce, and synchronize with the daily cycle. When the environment changes at 100,000 time units, both the size of the population and the average gathered energy drop, but then quickly recover. More importantly, by analyzing the percentage of synchronized agents, we can see that, although it takes longer to recover, the agents also resynchronize to the daily cycle. One might wonder if it would be the case that the agents are simply not entering caves. But the plot also shows that about 80% of the agents find at least one cave during their lifetime. Note that, as these percentages are taken from the whole population at a given time interval, and there are constantly new agents being born, the percentage could never rise to 100%. New agents will normally need some time to move before they find a cave.

Figure 4: Plot of the evolution of the total number of agents in the population, average gathered energy, percentage of agents in sync with the day cycle, and percentage of agents that found caves, over the course of one simulation run (number of caves is 50).

These results may seem counter-intuitive, as there doesn't seem to be any way for the agents to detect the caves. To clarify, we analyzed some agents' brains. In listing 3 and listing 4 we show two examples of agents' brains from the simulation run shown in figure 4. The first one is taken from an agent living in the environment without caves (time 84536), and the second is taken from the environment with caves and at a time where the agents have resynchronized (time 183513).

**Listing 3** Example of the structure of the brain of an agent born at time 84536, for the simulation run shown in figure 4. Used Rules are set in bold.

1. **IF Resource Location = 3 THEN turn right**
2. IF Light Level < Light Level THEN eat
3. IF Resource Location > 3 THEN eat
4. **IF Light Level < 26.5859 THEN sleep**
5. IF Light Level < 36.3748 THEN sleep
6. IF Light Level = 47.8427 THEN eat
7. **IF Feature energy > 16.7159 THEN reproduce**
8. IF Feature energy = 26.0336 THEN reproduce
9. IF Resource Location = 3 THEN eat
10. IF Light Level < Feature energy THEN sleep
11. **IF istru(Reaching Resource) THEN eat**
12. **IF Resource Location < 2 THEN turn left**
13. IF istru(Reaching Resource) THEN turn left
14. **IF not(Reaching Resource) THEN go front**
15. IF Resource Location > 1 THEN sleep
16. IF istru(Reaching Resource) THEN turn right
17. IF Light Level < 97.9668 THEN turn right

The analysis of the brain in listing 3 allows us to see that the agent has good food gathering behavior (rules 1, 11, 12, and 14), reproduces whenever it has more than 16.7159 energy (rule 7), and sleeps when the light level falls below 26.5859 (rule 4). If put in the environment with caves, this agent would clearly not survive, as it would fall asleep on a cave (from rule 4) and never wake up again.

Examining the brain presented in listing 4, we can finally see how the agents adapt to the environment with caves. The important rule in this case is the one at position 2. To explain the behavior induced by this rule, we need to take a closer look. Lets first consider that the agent is in a cave. If the agent doesn't have any resource within its vision range (very likely as in the cave the vision range is small), the value of *Resource Location* will be 0. As we know, in a cave the light level is equal to the minimum light level, which is 0. Therefore, this rule will make the agent move forward whenever it is inside a cave. In fact, we find this rule (or some small variation) in all the agents analyzed in runs where there is recovery of synchronization.

Figure 5: Plot of the evolution of the total number of agents in the population, average gathered energy, percentage of agents in sync with the day cycle, and percentage of agents that found caves, over the course of one simulation run (number of caves is 20).

The rest of the capabilities of the agent are also relatively easy to find in this rule list. From rules 1, 4, 13, and 14, we can see that the agent has a good foraging behavior. Rule 8 provides reproduction capabilities. And rule 16, when combined with rule 14, makes the agent sleep if the light level of the environment is less than 11.8449 and greater than 3 (maximum value for the *Resource Location* perception).

In table 2 we show an overview of the successful runs from all the tested simulation configurations. As stated earlier, we ran simulations with different values for the number of caves present in the environment. These results show that the configuration change doesn't seem to affect the number of successful runs out of the total of 30 runs. This was expected, as we were only changing the number of caves, which didn't affect the first environment. However, if we look at the number of runs where agents recover in the environment with caves, we find a different results for the three configurations. This is also rather straightforward to explain. With a smaller number of caves in the environment, the probability an agent has of finding a cave within its lifetime diminishes, making it easier maintain the synchronization from the first environment.

In figure 5 we show a run of the simulation with 20 caves. The plot is similar to that of figure 4, with the main difference being in the percentage of agents that find caves. In this case we can see that the percentage stabilizes at about 50%, whereas with the 50 cave configuration it stabilizes at about 80%. In the configuration with 10 caves, the percentage falls to about 30%. As expected, the less caves in the environment, the lower the probability of an agent finding a cave in its lifetime.

**Listing 4** Example of the structure of the brain of an agent born at time 183513, for the simulation run shown in figure 4. Used rules are set in bold

1. **IF istrue(Reaching Resource) THEN eat**
2. **IF Resource Location = Light Level THEN go front**
3. IF Light Level = 29.2361 THEN turn right
4. **IF Resource Location = 1 THEN turn left**
5. IF Resource Location < Resource Location THEN sleep
6. IF Feature energy < Feature energy THEN sleep
7. IF istrue(Reaching Resource) THEN eat
8. **IF Feature energy > 16.7159 THEN reproduce**
9. IF istrue(Reaching Resource) THEN reproduce
10. IF Light Level = Resource Location THEN eat
11. IF Light Level = 59.7254 THEN eat
12. IF istrue(Reaching Resource) THEN go front
13. **IF Resource Location = 2 THEN go front**

## Conclusion

Even though it seemed unlikely for the agents to distinguish “night” from “cave” with only the light level as an input perception, evolution found a way to use the “tools at hand” to solve the problem. In this case, the agents take advantage of a specific feature of the environment created. As the light level, when inside a cave, is always zero, and outside a cave, at night, it is between zero and ten, the agents adapted to that fact. It is important to note that the scenario was not designed with this in mind, and in that regard that behavior was unexpected. This result may have a parallel in the real world, where it is common to find species that take ad-

vantage of specific properties of the environment, creating niches.

We believe these results are mainly due to the open-ended nature of the model used. The inexistent explicit fitness function allows the modeler not to over-specify and guide the solution, giving more freedom to the evolutionary system to produce viable solutions. Also, when compared with a fixed structure neural network, the brain architecture used may provide some added flexibility, and allow for these unexpected behaviors to evolve.

Regarding future work, even though the simulations showed that the agents adapt to the new environment without an internal clock, it would still be interesting to incorporate a clock source in the architecture of the agents, and compare the results of the simulations.

With these experiments we continued our investigation into the evolution of complex behaviors through open-ended evolution simulations. Following the results from the previous simulations (Baptista and Costa, 2008), where we showed that using the model of the BitBang framework we are able to evolve complex behaviors, from random initial conditions, in an open-ended evolution environment, we now also show that by simply adding extra complexity to the simulated world, the agents continue to evolve new behaviors adapted to their new environmental conditions.

## Abstract

The ability to move in complex environments is a fundamental requirement for robots to be a part of our daily lives. While in simple environments it is usually straightforward for human designers to foresee the different conditions a robot will be exposed to, for more complex environments the human design of high-performing controllers becomes a challenging task, especially when the on-board resources of the robots are limited. In this article, we use a distributed implementation of Particle Swarm Optimization to design robotic controllers that are able to navigate around obstacles of different shape and size. We analyze how the behavior and performance of the controllers differ based on the environment where learning takes place, showing that different arenas lead to different avoidance behaviors. We also test the best controllers in environments not encountered during learning, both in simulation and with real robots, and show that no single learning environment is able to generate a behavior general and robust enough to succeed in all testing environments.

## Introduction

In simple environments, it is usually straightforward for human designers to anticipate the different conditions a robot will be exposed to. Thus, robotic controllers can be designed manually by simplifying the number of parameters or inputs used. However, for more complex environments, the human design of high-performing controllers becomes a challenging task. This is especially true if the on-board resources of the robot are limited, as humans may not be aware of how to exploit limited sensing capabilities.

Machine-learning techniques are an alternative to human design that can automatically synthesize robotic controllers in large search spaces, coping with discontinuities and nonlinearities, and find innovative solutions not foreseen by human designers. In particular, evaluative, on-board techniques can develop specific behaviors adapted to the environment where the robots are deployed.

The purpose of this paper is twofold. First, to verify whether different behaviors arise as a function of the learning environment in the adaptation of multi-robot obstacle avoidance. Secondly, to test how the learned behaviors perform in environments not encountered during learning, that

is, to evaluate how general are the solutions found in the learning process. The adaptation technique used is Particle Swarm Optimization (PSO) (Kennedy and Eberhart, 1995), which allows a distributed implementation in each robot, speeding up the adaptation process and adding robustness to failure of individual robots.

The remainder of this article is organized as follows. Section Background introduces some related work on PSO, and on the influence of the environment in robotic adaptation. In the Hypotheses and Methods section we propose two hypotheses that motivate our research and describe the experimental methodology used to test them. Section Results and Discussion presents the experimental results obtained and discusses the validity of the proposed hypotheses. Finally, we conclude the paper with a summary of our findings and an outlook for our future work.

## Background

The background for this article is divided into two subsections, one briefly introducing PSO and related work on distributed implementations and robustness in the presence of noise, and the second one dealing with environmental complexity and its role in the adaptation of robotic controllers.

## Particle Swarm Optimization

PSO is a relatively new metaheuristic originally introduced by Kennedy and Eberhart (1995), which was inspired by the movement of flocks of birds and schools of fish. Because of its simplicity and versatility, PSO has been used in a wide range of applications such as antenna design, communication networks, finance, power systems, and scheduling. Within the robotics domain, popular topics are robotic search, path planning, and odor source localization (Poli, 2008).

PSO is well suited for distributed/decentralized implementation due to its distinct individual and social components and its use of the neighborhood concept. Most of the work on distributed implementation has been focused on benchmark functions running on computational clusters (Akat and Gazi, 2008; Rada-Vilela et al., 2011). Implemen-

tations with mobile robots are mostly applied to odor source localization (Turduv and Atas, 2010; Marques et al., 2006), and robotic search (Hereford and Siebold, 2007), where the particles' position is usually directly matched to the robots' position in the arena.

Most of the research on optimization in noisy environments has focused on evolutionary algorithms (Jin and Branke, 2005). The performance of PSO under noise has not been studied so extensively. Parsopoulos and Vrahatis (2001) showed that standard PSO was able to cope with noisy and continuously changing environments, and even suggested that noise may help to avoid local minima. Pan et al. (2006) proposed a hybrid PSO-Optimal Computing Budget Allocation (OCBA) technique for function optimization in noisy environments. Pugh and Martinoli (2009) showed that PSO could outperform Genetic Algorithms on benchmark functions and for certain scenarios of limited-time learning in the presence of noise.

In our previous work (Di Mario and Martinoli, 2012), we analyzed in simulation how different algorithmic parameters in a distributed implementation of PSO affect the total evaluation time and the resulting fitness. We proposed guidelines aiming at reducing the total evaluation time so that it is feasible to implement the adaptation process within the limits of the robots' energy autonomy.

### Role of the Environment

Regarding complexity, Al-Kazemi and Habib (2006) analyzed the internal behavior of PSO when the dimension of the problem is increased. They used different metrics to conclude that the PSO particles behave in a similar way independently of the complexity of the problem. Auerbach and Bongard (2012) studied the relationship between environmental and morphological complexity in evolved robots, showing that many complex environments lead to the evolution of more complex body forms than those of robots evolved in simple environments.

Nolfi (2005) proposed that the behavior of a robot (and of any other agent) depends on the interaction between its controller, its body, and the external environment (that can also consist of other robots). These interactions are non-linear and affect the behaviors as well as the learning process.

Nolfi and Parisi (1996) evolved neural network controllers for robotic exploration, switching between two different environments during the evolution process. They evolved two different neural networks: with and without the capability to learn how to behave in the environment where the robot is placed. Different behaviors resulted from evolution depending on whether learning was allowed and on the environment where the robots were tested.

Islam and Murase (2005) evolved a robotic controller for obstacle avoidance and used tools from chaos theory (return maps and Lyapunov exponents) to measure the complexity of the resulting behaviors in the learning environment and

other testing environments.

Nelson et al. (2003) evolved robotic controllers while increasing the complexity of the environments during evolution. They compared the resulting fitness and evolution process with evolution performed only in the most complex world.

Berlanga et al. (2002) studied a coevolutionary method for robot navigation where the initial positions of the robots used for evolving the controllers are also evolved. They evolved solutions for several environments (in most cases of similar complexity), and tested their fitness in the arena where each controller was evolved as well as in the remaining arenas. They did not find significant performance differences between the controllers, probably due to the similar complexity of the arenas used for learning.

## Hypotheses and Methods

This article discusses how the environment affects the adaptation of controllers for multi-robot obstacle avoidance using a distributed implementation of PSO. Robots navigate autonomously in the presence of other robots in square arenas with obstacles of different size and shape. We look at the different environments where learning takes place, analyze the resulting behaviors, and test how the controllers perform in the environments where they did not previously learn.

### Hypotheses

The experiments conducted in this paper are motivated by the following hypotheses regarding the influence of the environment in the adaptation of robotic controllers:

**Hypothesis 1** *Different environments lead to different behaviors of the adapted controllers. This might be specially significant for considerably different environments (e.g., empty arena vs. very narrow corridor).*

**Hypothesis 2** *Some learning environments may generate more robust controllers that perform better in situations not encountered during learning. This leads to the problem of choosing the correct environment (or set of environments) for the adaptation process in order to make the resulting controller robust to variations in the environment.*

### Fitness Function

We use a metric of performance based on the work of Floreano and Mondada (1996), which is present in several studies on learning obstacle avoidance (e.g., Lund and Miglino (1996), Pugh and Martinoli (2009), Palacios-Leyva et al. (2013), and our own previous work Di Mario and Martinoli (2012)). The fitness function consists of three factors, all normalized to the interval [0, 1]:

$$f = f_v \cdot (1 - \sqrt{f_i}) \cdot (1 - f_i) \quad (1)$$

$$f_v = \frac{1}{N_{eval}} \sum_{k=1}^{N_{eval}} \frac{\max\{v_{l,k} + v_{r,k}, 0\}}{2} \quad (2)$$

$$f_t = \frac{1}{N_{eval}} \sum_{k=1}^{N_{eval}} \frac{|v_{l,k} - v_{r,k}|}{2} \quad (3)$$

$$f_i = \frac{1}{N_{eval}} \sum_{k=1}^{N_{eval}} i_{max,k} \quad (4)$$

where  $\{v_{l,k}, v_{r,k}\}$  are the normalized speeds of the left and right wheels at time step  $k$ ,  $i_{max,k}$  is the normalized proximity sensor activation value of the most active sensor at time step  $k$ , and  $N_{eval}$  is the number of time steps in the evaluation period. This function rewards robots that move forwards quickly ( $f_v$ ), turn as little as possible ( $f_t$ ), and stay away from obstacles ( $f_i$ ).

### Experimental Platform

Our experimental platform is the Khepera III, a differential wheeled robot with a diameter of 12 cm. It is equipped with nine infra-red sensors for short range obstacle detection, which in our case are the only external inputs for the controllers, and two wheel encoders, which are used to measure the wheel speeds for the fitness calculations.

Since the response of the Khepera III proximity sensors is not a linear function of the distance to the obstacles, the proximity values are inverted and normalized using measurements of the real robot sensor's response as a function of distance. This inversion and normalization results in a proximity value of 1 when touching an obstacle, and a value of 0 when the distance to the obstacle is equal to or larger than 10 cm.

Simulations are performed in Webots (Michel, 2004), a realistic physics-based submicroscopic simulator that models dynamical effects such as friction and inertia. In this context, by submicroscopic we mean that it provides a higher level of detail than usual microscopic models, faithfully reproducing intra-robot modules (e.g., individual sensors and actuators).

### Controller Architecture

The controller architecture used is a recurrent artificial neural network of two units with sigmoidal activation functions  $s(\cdot)$ . The outputs of the units determine the wheel speeds  $\{v_{l,t}, v_{r,t}\}$ , as shown in Equation 5. Each neuron has 12 input connections: the 9 normalized infrared sensors values  $\{i_1, \dots, i_9\}$ , a connection to a constant bias speed, a recurrent connection from its own output, and a lateral connection from the other neuron's output, resulting in 24 weight parameters in total  $\{w_0, \dots, w_{23}\}$ .

$$\begin{aligned} v_{l,t} &= s(w_0 + \sum_{k=1}^9 i_k \cdot w_k + w_{10} \cdot v_{l,t-1} + w_{11} \cdot v_{r,t-1}) \\ v_{r,t} &= s(w_{12} + \sum_{k=1}^9 i_k \cdot w_{k+12} + w_{22} \cdot v_{l,t-1} + w_{23} \cdot v_{r,t-1}) \end{aligned} \quad (5)$$

### Environments

We conduct experiments in four different environments, shown in Figure 1. The first one is an empty square arena of 2 m x 2 m, where the walls and the other robots are the only obstacles. The second and third environments are based on the same bounded arena, where cylindrical obstacles of two sizes are added in different numbers. The second environment has 20 medium-sized obstacles (diameter 10 cm), while the third has 40 small-sized obstacles (diameter 2 cm). The fourth environment is the same size as the empty arena with an inner wall of 1.5 m creating a continuous corridor of 25 cm width.

In simulation, the cylindrical obstacles are randomly repositioned before each fitness evaluation, meaning that the second and third environments are dynamic. In real-robot experiments, the obstacles are kept in fixed positions, the variation between runs is provided by the randomized initial pose of the robots. The third environment was not tested with real robots given the difficulty of keeping such thin cylinders vertical during collisions, but it should be noted that this kind of obstacles can occur in real environments, for example in the case of a chair or table with very thin legs.

All experiments are conducted with 4 robots. The method for initializing the robots' pose for each fitness evaluation is different between simulation and experiments with real robots. In simulation, the initial positions are set randomly with a uniform probability distribution, verifying that they do not overlap with obstacles or other robots. For the experiments with real robots, in the empty arena a random speed is applied to each wheel for three seconds to randomize the robots' pose. In the two arenas with obstacles and in the corridor one, the robots are manually repositioned to avoid disturbing the location of the obstacles, and then the robots turn in place with a random speed for two seconds to randomize their orientation.

### Adaptation Algorithm

The optimization problem to be solved by the adaptation algorithm is to choose the set of weights  $\{w_0, \dots, w_{23}\}$  of the artificial neural network controller such that the fitness function  $f$  as defined in Equation 1 is maximized. The chosen algorithm is the distributed, noise-resistant variation of PSO introduced by Pugh and Martinoli (2009), which operates by re-evaluating personal best positions and aggregating them with the previous evaluations (in our case a regular

Figure 2: Noise-resistant PSO algorithm

average performed at each iteration of the algorithm). The pseudocode for the algorithm is shown in Figure 2.

The position of each particle is a 24-dimensional real-valued vector that represents the weights of the artificial neural network. The velocity of particle  $i$  in dimension  $j$  (shown in Equation 6) depends on three components: the velocity at the previous step weighted by an inertia coefficient  $w_I$ , a randomized attraction to its personal best  $x_{i,j}^*$  weighted by  $w_P$ , and a randomized attraction to the neighborhood's best  $x_{p',j}^*$  weighted by  $w_N$ .  $rand()$  is a random number drawn from a uniform distribution between 0 and 1. The position of each

particle is updated according to Equation 7.

$$v_{i,j} := w_I \cdot v_{i,j} + w_P \cdot rand() \cdot (x_{i,j}^* - x_{i,j}) + w_N \cdot rand() \cdot (x_{p',j}^* - x_{i,j}) \quad (6)$$

$$x_{i,j} := x_{i,j} + v_{i,j} \quad (7)$$

The algorithm is implemented in a distributed fashion, which reduces the total evaluation time required by a factor equal to the number of robots. Even if the learning in this paper is performed only in simulation, the algorithm can easily be executed completely on-board with very low requirements in terms of computation and communication.

Each robot evaluates in parallel a possible candidate solution and shares the solution with its neighbors in order to create the next pool of candidate solutions. The neighborhood presents a ring topology with one neighbor on each side. Particles' positions and velocities are initialized randomly with a uniform distribution in the  $[-20, 20]$  interval, and their maximum velocity is also limited to that interval.

The PSO algorithmic parameters are set following the guidelines for limited-time adaptation we presented in our previous work (Di Mario and Martinoli, 2012) and are shown in Table 1.

## Results and Discussion

The results of this article are presented as follows. First, we perform the learning in simulation in the four environments previously mentioned. Then, the best controller from each learning environment is tested in every environment in simulation. Finally, the four controllers from each learning

Table 1: PSO parameter values

Parameter	Value
Number of robots $N_{rob}$	4
Population size $N_p$	24
Iterations $N_i$	200
Evaluation span $t_e$	40 s
Re-evaluations $N_{re}$	1
Personal weight $w_p$	2.0
Neighborhood weight $w_N$	2.0
Dimension $D$	24
Inertia $w_I$	0.8
$V_{max}$	20

environment are also tested with real robots in three of the four environments.

### Learning in Simulation with PSO

Since PSO is a stochastic optimization method and the performance measurements are noisy, each PSO optimization run may converge to a different solution. Therefore, for statistical significance, we performed in simulation 100 PSO adaptation runs for each learning environment. Figure 3 shows the progress of the PSO learning at each iteration for the four environments. Vertical bars show the standard deviation among the 100 PSO runs.

The highest performance corresponds to the empty arena since it is the easiest environment with just the bounding walls and the other robots acting as obstacles. The fitness in both environments with cylindrical obstacles is very similar for the whole learning process. The slowest learning rate occurs for the narrow corridor, indicating that this environment is more challenging for the learning algorithm. By the end of the adaptation process the performance is slightly lower than in the arenas with cylindrical obstacles.

It should be noted that the learning environment has a significant impact in the variation between runs, as the standard deviation is lowest in the empty arena and it increases markedly for the more complex environments.

Trajectories can be a useful tool to identify the behavior of the robots, as we have seen in our previous work (Di Mario et al., 2011). Figure 4 shows the resulting trajectories of the best learned behaviors in simulation for each environment where adaptation took place. It can be seen how in the empty arena and in the medium-sized obstacles arena the robot trajectories are straight until they find an obstacle (wall, cylindrical obstacle, or other robot), performing then a sharp turn and continuing straight afterwards.

The trajectory learned in the arena with small-sized obstacles is curvilinear when there are no obstacles within range. When the robot detects an obstacle, it makes a sharp turn to later continue its curvilinear movement. The small obstacles are thinner than the distance between two contiguous infrared sensors, so sometimes the robots are not able to detect

Figure 3: Best fitness found at each iteration for 100 PSO optimization runs. Bars represent the standard deviation across runs. Fitness in empty arena in blue (env 1). Fitness in arena with 20 medium cylindrical obstacles in red (env 2). Fitness in arena with 40 small cylindrical obstacles in black (env 3). Fitness in corridor arena in green (env 4).

them. Curvilinear movements may help in avoiding getting stuck in front of the small obstacles, and thus the behavior learned with PSO does not involve moving in straight lines as in the other cases.

In the corridor arena, the robot moves along the corridor, turning 90 degrees to head into the following sub-corridor, and thus exploring the whole arena.

As we conjectured in Hypothesis 1, the different environments cause the robots to learn different behaviors. In the next section we will show how the learned controllers behave in the other environments that were not encountered during learning.

### Testing in Simulation

In the previous section, we obtained four different controllers corresponding to each environment where learning took place. In this section, we test the controllers in all environments to see how they perform in situations not encountered while learning, i.e., to see how general and robust are the obtained behaviors.

Figure 5a shows the boxplot of the fitness of 20 evaluation runs performed in simulation for each controller and testing environment. Since all experiments are conducted with 4 robots, this results in 80 fitness measurements per controller and environment. For the sake of brevity, we use  $T$  to denote testing environment,  $L$  for learning environment, and we number the environments from one to four in the following order: empty arena, arena with 20 medium cylindrical obstacles, arena with 40 small cylindrical obstacles and

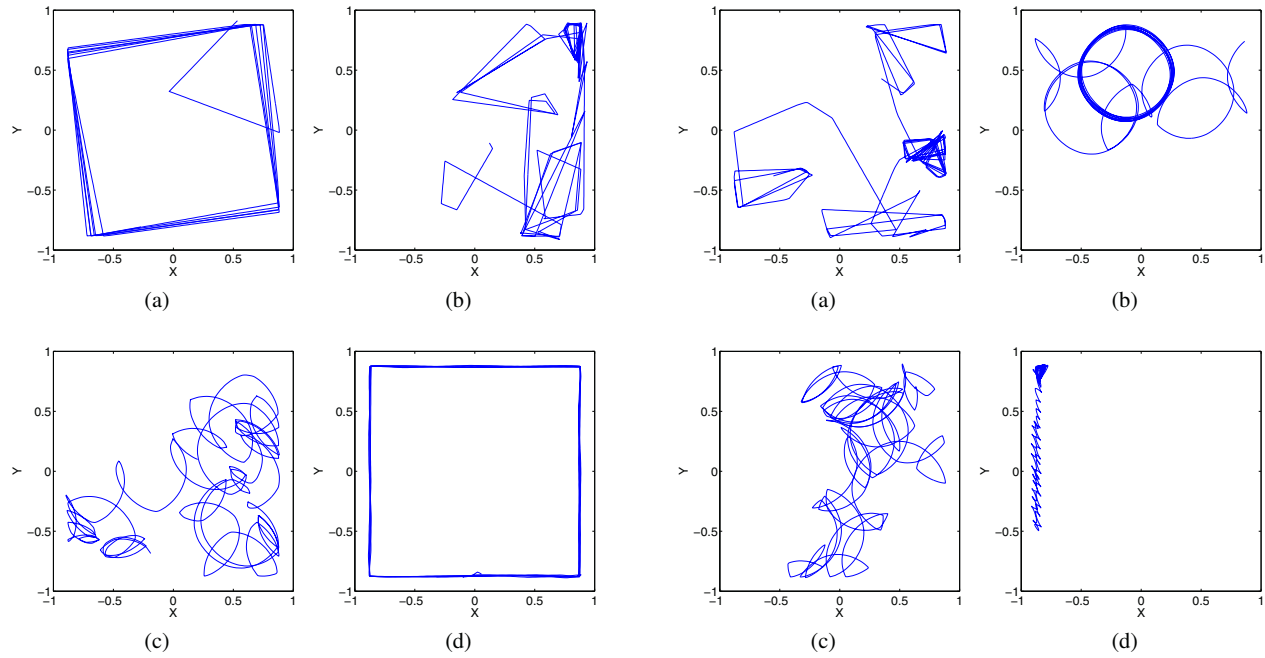

Figure 4: Trajectories of one of the four robots during a single experiment in simulation for the controllers learned in the four environments under study. (a) Empty arena. (b) Medium sized obstacles arena. (c) Small sized obstacles arena. (d) Corridor arena.

corridor arena. Thus,  $T1L4$  for instance should be read as: test performed in the empty environment with the controller learned in the corridor environment.

As expected, for each environment, the controller learned in the testing environment has the highest performance. However, for the simplest environment ( $T1$ ), there is no significant difference between the performance of controllers  $L1$ ,  $L2$ , and  $L4$ . Regarding Hypothesis 2 concerning the generality of the learned behaviors, controller  $L4$  seems to be the most robust, as it significantly outperforms all other controllers in the corridor and still performs almost as good as  $L1$  in  $T1$  and reasonable well in  $T2$ , although it performs poorly in  $T3$ .

Further insight on the performances can be obtained by analyzing the trajectories described by the robots in the different environments. Out of the 16 evaluation conditions, we show the ones we consider most interesting in Figure 6.

The behavior of controller  $L1$  is similar to that of controller  $L2$  in all testing environments (for example, compare the trajectories from Figure 6a and Figure 4b), since they employ similar avoidance strategies: moving in straight lines and making sharp turns near obstacles. This result becomes evident when considering that the medium-sized cylindrical obstacles are very similar in shape and size to

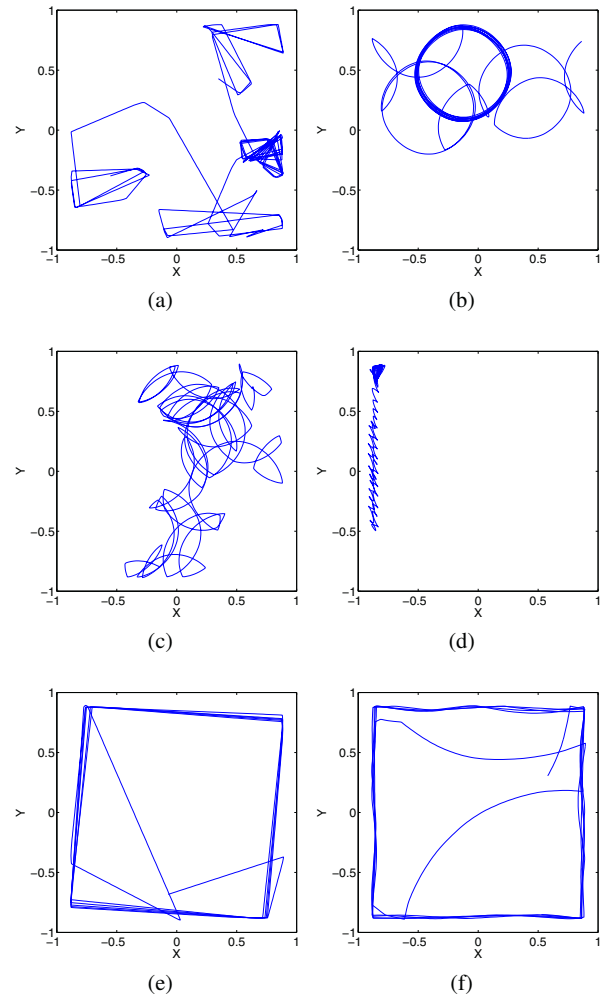

Figure 6: Trajectories of one of the four robots during a single experiment in simulation for different learned controllers (LX) and testing environments (TX). (a) T2L1. (b) T1L3. (c) T2L3. (d) T4L3. (e) T1L4. (f) T1L4\*.

the Khepera III robot. However, maybe due to the higher obstacle density of Environment 2, controller  $L2$  is more robust in the sense that it performs better in environments 3 and 4.

The curvilinear behavior of controller  $L3$ , which enables it to avoid very thin obstacles, is also observed with the larger obstacles of Environment 2 (Figure 6c), and results in fully circular trajectories in the empty environment (Figure 6b). However, this controller as well as controllers  $L1$  and  $L2$  were not able to move along the corridor, doing instead short straight movements alternated with sharp turns (Figure 6d).

Controller  $L4$  was the only one able to move smoothly along the corridor in Environment 4, performing well in all environments except  $T3$ . The behavior learned can be ob-

Figure 5: Boxplot showing the fitness of the four learned controllers (L1-L4). (a) Evaluated in the four testing environments (T1-T4) in simulation. (b) Evaluated in three testing environments (T1, T2 and T4) with real robots. The box represents the upper and lower quartiles, the line across the middle marks the median, and the crosses show outliers.

served when tested in the empty environment (*T1L4*) in Figure 6e. The robot moved straight performing a 90 degree sharp turn when finding an obstacle. This exact 90 degree turn was learned in the corridor environment to perform the transition from one sub-corridor to another.

As mentioned previously, we run 100 PSO runs for each environment, and controller *L4* is the best-performing one from the 100 runs in the corridor environment, but we noticed that not all the resulting controllers have the same behavior. A different controller resulting from the corridor environment is shown for the empty arena (*T1L4\**) in Figure 6f. The robot learned a wall-following behavior, performing a curvilinear movement in the absence of obstacles.

However, when testing this controller in the corridor (*T4L4\**) the trajectory looks exactly the same as the one from *T4L4*. Thus, it is interesting to notice that this behavior could only be observed when testing in other environments than the learning one, which shows the importance of using varied environments to observe the whole range of behaviors of a given controller.

### Testing with Real Robots

In order to validate the results obtained in simulation, we tested the same controllers with real robots in environments 1, 2, and 4. We did 20 evaluation runs with 4 robots, leading to 80 fitness measurements per case. The resulting fitness is shown in Figure 5b.

As in simulation, the performance of controllers *L1* and *L2* was similar. Again, controller *L4* seemed to be the most robust, outperforming all other controllers in the corridor and performing similarly to the best controllers in the other

two environments.

Controller *L3* suffered a noticeable performance drop when going from simulation to reality due to an unmodeled effect: the Khepera III motors' were not able to work smoothly at low speeds, and thus the inner wheel in the circular movements in open spaces was practically stopped, resulting in circles with a very small radius.

Finally, controller *L4* was also able to move along the corridor as in simulation, although the behavior was not as smooth and turns midway through the corridor were more frequent than in simulation (probably due to inaccuracies in the sensor model and the increased noise in real environments). Thus, the real-world performance was much lower.

### Conclusion

In this paper, we studied the effect of the environment on the multi-robot learning of an obstacle avoidance behavior. We showed that the same controller architecture, fitness function, and learning algorithm implemented in different environments lead to different avoidance behaviors, such as moving in straight lines with sharp turns, curvilinear movements, and wall-following around obstacles. We then tested the learned controllers in environments not encountered during learning, both in simulation and with real robots, which allowed us to see the full range of behaviors of each controller. Finally, we saw that no single learning environment was able to generate a behavior general enough to succeed in all testing environments.

As future work, we intend to study the interplay between architectural complexity and capability of generalization. In other words, we would like to know how to design a learn-

ing environment, or maybe a set of environments if required, that lead to general and robust avoidance behaviors while maintaining the architecture complexity low. It would also be interesting to study the interplay between a certain fitness function and the required architecture complexity. This work is part of our ongoing effort to develop distributed, noise-resistant adaptation techniques that can optimize high-performing robotic controllers quickly and robustly.

## Abstract

Intrusion detection is an essential mechanism to protect wireless sensor networks against internal attacks that are relatively easy and not expensive to mount in these networks. Recently, we proposed, implemented and tested a framework that helps a network operator to find a trade-off between detection accuracy and usage of resources that are usually highly constrained in wireless sensor networks. We used a single-objective optimization evolutionary algorithm for this purpose. This approach, however, has its limitations. In order to eliminate them, we show benefits of multi-objective evolutionary algorithms for intrusion detection parametrization and examine two multi-objective evolutionary algorithms (NSGA-II and SPEA2). Our examination focuses on the impact of an evolutionary algorithm (and its parameters) on the optimality of found solutions, the speed of convergence and the number of evaluations.

## Introduction

Recent advances in wireless communications and low-cost electronic devices enabled the development of *low-cost* and *high-performance wireless* networking technologies. Apart from widely used *cellular networks* known from mobile phones and *infrastructure local area networks*, there are also *ad hoc networks* operating without any given and fixed infrastructure, where the connections are established on demand in ad hoc manner (Dressler, 2007).

*Wireless sensor networks* (WSNs) can be considered as a type of ad hoc wireless networks with many specifics. The main difference against the “ordinary” ad hoc wireless networks is that the WSNs consist of a large number of usually *homogeneous, low-cost* and *resource restricted sensor nodes*. Their goal is to measure physical parameters like temperature, humidity, intensity of light, and send it to a *base station* (BS) for further processing. Since a node communication range is limited to tens of meters and it is not always feasible for the node to directly communicate with the BS, measurements are usually sent hop-by-hop from one node to another until they reach the BS.

Since WSNs are often deployed in physically open and sometimes even hostile environments, they can be subject to various security attacks ranging from *passive eavesdropping*

to *active* interfering (Zhang and Lee, 2000). An active attacker may insert a node in a network, or capture and reprogram an existing one in order to, e.g., drop, delay, modify or reorder packets containing important sensor measurements or routing information (Karlof and Wagner, 2003).

An *intrusion detection system* (IDS) is an essential mechanism to protect a network against internal attacks. Sensor nodes can monitor only a small part of their surrounding. Hence, to enable intrusion detection even in the remote parts of the network, *intrusion detection agents* should be deployed at different nodes in all parts of the network to monitor malicious events *locally*, in a distributed fashion (da Silva et al., 2005; Roman et al., 2006).

An IDS for a WSN should be highly optimized for a given application scenario, i.e., it should not consume more energy (memory) than it is necessary to achieve a required level of detection accuracy. Otherwise, a higher detection accuracy will be at the expense of resources that are highly constrained in sensor nodes. For example, MICAz – a typical sensor node – is equipped with the 8 MHz Atmel Atmega128L microcontroller, 4 kB RAM, 512 KB flash memory, 802.15.4 compliant Texas Instruments CC2420 transceiver and two AA batteries (Crossbow, 2013).

One can expect different requirements in network security and resource consumption for different applications, e.g., one for emergency-response and another for agriculture. Since there is a variety of application scenarios, a single set of IDS parameters is not optimal for all of them. In (Stetsko, 2012), a framework that optimizes the parameters of an IDS for a given application scenario in terms of the detection accuracy and resource consumption was presented. The optimization was driven by multiple objectives that were represented by different evaluation metrics (e.g., number of true positives, number of true negatives, memory usage). A single-objective optimization algorithm was used with the need to provide weights for each objective before the optimization process takes place. If the network operator wants to change weights, the optimization process should run again.

In this work, we examine two multi-objective evolution-

ary algorithms (MOEAs) that eliminate the limitation mentioned above. Our contribution is threefold. First, we show that MOEAs can be utilized for optimization of an IDS in WSNs. Second, we compare effectiveness of NSGA-II and SPEA2 for our scenario that is described in the following sections. Third, we evaluate the impact of MOEA parameters on the optimization process.

## Optimization Framework for WSN

In this section, we present our optimization framework that can be used for optimization of various detection techniques in WSNs. It consists of a *simulator* that simulates a specific configurable scenario of a WSN and provides statistics of the simulation. The statistics are input for an *optimization engine* that, based on them, designs new WSN configurations and provides them back to the simulator for further evaluation. The conceptual architecture of the framework is discussed in details in (Stetsko, 2012). In the following subsections, we present our use case that is consistent for all experiments discussed farther in this paper.

### Simulator

We evaluate the performance of the IDS using the MiXiM simulator (Köpke et al., 2008) based on the OMNeT++ platform. In the past, we made a thorough comparison of available simulators for WSNs in (Stetsko et al., 2011). The MiXiM simulator provides complex and realistic models suitable for our research. The simulation models are following: *wireless channel* and *network topology* models regarding the global aspects of the WSN and models of *network*, *data link* and *physical* layers and *energy consumption* models of the sensor nodes.

In our case, we simulate a WSN consisting of sensor nodes equipped with the CC2420 transceiver (widely used by MICAz and TelosB platforms) in an open environment. The description of settings of different simulation models follows:

- *Wireless channel model* – An open changing environment is simulated using the *log-normal shadowing* model (Rapaport, 2001) that is the most widely used wireless channel model among the simulators (Stetsko et al., 2011). The pass loss exponent representing the signal propagation was set up to 2 (outdoor environment). The variations in received signal are reflected by a Gaussian random variable with zero mean and standard deviation set up to 2. The time interval of the changes was set up to 0.001 s.
- *Network topology model* – Static topology with random uniform distribution of the sensor nodes in 2D square area is used in the experiments.
- *Network layer* – The network layer uses static routing tree generated using the following algorithm. A base station

broadcasts a packet containing its identification together with the value  $h$  (number of hops to the base station) set to 0. A node waits until it receives a packet from a neighbour that is the closest one (has the highest signal strength). Then the node sets the neighbour as its parent, increases value  $h$  by 1 and broadcasts the value together with its identification.

- *Data link layer* – Protocol CSMA-CA according to the IEEE 802.15.4 standard is used.
- *Physical layer* – The radio model represents the CC2420 transceiver that is compliant to the IEEE 802.15.4 standard and is used by MICAz and TelosB sensor nodes. The transmitting power is set up to -25 dBm (0.00316227766017 mW) for all sensor nodes.
- *Energy consumption* – The energy consumption is not taken into account in this paper because we do not use any sleep mode of the nodes' transceivers that saves the energy in presented detection technique.

### Optimization Engine

Various metaheuristics can be used to generate new candidate IDS configurations based on the previous ones evaluated by the simulator. We use *evolutionary algorithms* (EAs) as we found them advantageous in our previous work (Stetsko, 2012). The new generation of candidate configurations is evaluated by the simulator and the process continues until some stopping criterion is fulfilled (in our case predefined number of generations). In this paper, we show how the *multi-objective* approach can be utilized for IDS optimization in WSN. The MOEAs are discussed in section "Optimization Using MOEA". For experiments in this paper, we use a framework for metaheuristics ParadisEO (INRIA Lille, 2013; Liefvooghe et al., 2011).

### Distributed Computation

Apart from optimization using MOEAs, we decided to perform also *exhaustive search* for all our experiments. Since it is computationally demanding, we use the BOINC distributed computing platform (Anderson, 2001). We expect the network operators to optimize even more complex scenarios, where the exhaustive search would be unfeasible. However, to allow for a thorough comparison of the MOEAs, as one of the goals of this paper, we precomputed all configurations using BOINC on several tens of CPUs.

### Intrusion Detection System

In our optimization scenario, we use a detection technique the goal of which is to reveal malicious sensor nodes that execute *selective forwarding attack* where the attacker forwards only a fraction of received packets (Karlof and Wagner, 2003). In this kind of attack, it is assumed that the traffic is routed also through these malicious nodes. These nodes

are supposed to forward the packets received from their children to their parents towards the BS. The intent of the malicious nodes is to filter the traffic and forward only some packets which are selected randomly or based on some criteria (e.g., based on the data content of the packets to suppress information on some specific event in the environment).

### Detection Technique

We use a simple but *configurable* technique for detection of selective forwarding attack. Following notations are used in the text to explain the functionality of our IDS:

**Notation 1** The set  $A = \{a_1, \dots, a_{n_m}\}$  is a set of all malicious nodes in a network.

**Notation 2** The set  $C = \{c_1, \dots, c_{n_b}\}$  is a set of all benign nodes in a network.

**Notation 3** The function  $x : \mathbb{N} \rightarrow \mathbb{N}$  takes a sensor node index as an argument, and returns a number of the neighbours that consider this node benign.

**Notation 4** The function  $y : \mathbb{N} \rightarrow \mathbb{N}$  takes a sensor node index as an argument, and returns a number of the neighbours that consider this node malicious.

**Notation 5** The function  $n : \mathbb{N} \rightarrow \mathbb{N}$  takes a sensor node index as an argument, and returns a number of the neighbours of this node.

**Notation 6** The function  $m : \mathbb{N} \rightarrow \mathbb{N}$  takes a sensor node index as an argument, and returns the amount of memory (in bytes) used by an IDS on this node.

An IDS is running on a sensor node and continuously analyzing sent and overheard packets. A monitoring node  $c_i \in C$  overhears to some extent both incoming and outgoing packets of all close enough monitored neighbours  $b_j \in C \cup A$ . Note that the set of monitored neighbours is a subset of all neighbours limited to  $p_1$  (*max monitored nodes*). Neighbour of the node  $c_i$  is every node  $b_k \in C \cup A$ , such that  $c_i$  overheard at least one packet from  $b_k$  during the simulation. An IDS stores a table, where each of  $p_1$  rows corresponds to a certain monitored node. The table contains the number of packets received (PR) and forwarded (PF) by a monitored node.

If the IDS on a node  $c_i$  overhears a packet P sent to a monitored node  $b_j$  and  $b_j$  should forward the packet (e.g.,  $b_j$  is not a base station), then the IDS stores P in the buffer and increments the PR counter of the monitored node  $b_j$ . The number of buffered packets is limited by  $p_2$  (*buffer size*). If a new packet arrives but the buffer is full, the oldest packet is removed from the buffer. When the IDS overhears the packet P being forwarded by the node  $b_j$ , it removes P from the buffer (if it is still there) and increments the PF counter of the node  $b_j$ . Since both the table and the buffer are limited by parameters  $p_1$  and  $p_2$ , respectively, the IDS monitors only the closest nodes and the latest packets.

The detection is done at the end of the simulation, based on the collected statistics. The node  $c_i$  considers the node  $b_j$  as a selective forwarder if the dropping ratio of  $b_j$ , i.e., ratio of a number of packets dropped to a number of packets received, is higher than  $p_4$  (*detection threshold*). If the node  $c_i$  overheard less than  $p_3$  (*min received packets*) packets received by the node  $b_j$  during the simulation, the node  $b_j$  cannot be considered malicious by the node  $c_i$  because the number of overheard packets is small and there is a high level of uncertainty. In this case, the node  $b_j$  is considered benign. Note that the node  $c_i$  considers the neighbour node  $b_k$  benign if it is not a *monitored neighbour*. To summarize it, the detection decision is based on the following conditions:

- A node  $b_j$  is considered *malicious* by the neighbour node  $c_i$  if node  $b_j$  is the *monitored neighbour* and the observed dropping ratio is higher or equal to the *detection threshold* and the node  $c_i$  overheard at least *min received packets* addressed to the node  $b_j$ .
- A node  $b_j$  is considered *benign* by the neighbour node  $c_i$  if node  $b_j$  is not the *monitored neighbour* or if the dropping ratio is lower than the *detection threshold* or the IDS overheard less than *min received packets* addressed to the node  $b_j$ .

The IDS parameters that we optimize are shown in Table 1. The number of minimum received packets is in the range of  $\langle 1, 100 \rangle$  and detection threshold can be set from all packets dropped to all packets forwarded. The other parameters are discussed in the following subsection.

Name	Description	Range	Step
$p1$	<i>Max monitored nodes</i>	$\langle 1, 50 \rangle$	1
$p2$	<i>Buffer size</i>	$\langle 1, 50 \rangle$	1
$p3$	<i>Min received packets</i>	$\langle 1, 100 \rangle$	1
$p4$	<i>Detection threshold</i>	$\langle 0.01, 1 \rangle$	0.01

Table 1: The list of IDS parameters.

### Memory Consumption

The detection accuracy is influenced by the amount of memory allocated for the IDS. Each sensor node  $j$  requires the following amount of memory (in bytes) for the IDS:

$$m(j) = 8 * p_1 + 16 * p_2, \quad (1)$$

where 8 bytes are required for every monitored neighbour (4 B for node ID, 2 B for PR counter and 2 B for PF counter) and 16 bytes are required for one slot in the buffer (4 B for source address, 4 B for receiver address, 4 B for destination address in a case of multiple BSs in the WSN and 4 B for unique ID of a packet).

We determined the upper bound for the number of nodes being monitored by an IDS agent to 50. Table of neighbours can occupy 400 B ( $50 * 8 \text{ B} = 400 \text{ B}$ ) at maximum. That would be already 10% of MicaZ RAM (4 kB). Additional memory is needed for the buffered packets. We set the upper bound of the buffer size to 50 because the proof-of-concept experiments showed that bigger sizes did not influence the IDS accuracy. Thus,  $50 * 16 \text{ B} = 800 \text{ B}$  can be allocated for the buffer at maximum that is 20% of the RAM.

## Optimization Using MOEA

In this section, we show how MOEAs can be utilized for optimization of intrusion detection systems in complex environments of wireless sensor networks.

MOEAs can be useful for optimization of IDSs and other aspects in WSNs, providing the network operators with a set of *non-dominated* solutions. Then the network operator can choose between, e.g., an optimized solution  $A$  with better IDS accuracy at the cost of higher memory consumption and another optimized solution  $B$  with lower memory consumption at the cost of worse IDS accuracy. The set of non-dominated optimal solutions is called *Pareto front* (Talbi, 2009) and the goal of the MOEAs is to find a good approximation of the true Pareto front.

Several MOEAs producing approximations of the true Pareto front have been proposed. However, a good MOEA should produce solutions close to the true Pareto front with high *diversity* and should *converge* in a relatively short time. The *Non-dominated Sorting Genetic Algorithm II* (NSGA-II) proposed in (Deb et al., 2002) and the *Strength Pareto Evolutionary Algorithm 2* (SPEA2) proposed in (Zitzler et al., 2001) belong to the most widely used MOEAs (Talbi, 2009) and we compare them in this paper. Both algorithms are implemented in the evolutionary framework ParadisEO and also in MOGALib (MOGALib, 2013).

NSGA-II features two main criteria to provide good *convergence* and *diversification*, respectively: 1) *ranking using non-dominance concept* to sort the solutions according to the number of other solutions they are dominated by; and 2) *crowding distance* to keep the solutions spread as far from each other as possible.

The fitness values calculated for the solutions found by SPEA2 are based on the number of dominating solutions and their strength of dominance (to achieve *convergence*) and on the density estimation function (to achieve *diversification*).

## Objective Space

In the optimization of our IDS, we consider three following objective functions: number of false positives  $fp$ , number of false negatives  $fn$ , amount of consumed memory  $mem$ .

**Objective function 1.** The number of *false negatives* ( $fn$ ) of a solution  $x$  is calculated as follows:

$$fn(x) = \frac{1}{|A|} * \sum_{a_i \in A} \frac{x(a_i)}{n(a_i)}. \quad (2)$$

The values of  $fn$  range from 0 to 1. If every malicious node in the network is correctly detected by all of its neighbours,  $fn$  is equal to 0 and if none of malicious nodes is detected by any of its neighbours,  $fn$  is equal to 1.

**Objective function 2.** The number of *false positives* ( $fp$ ) of a solution  $x$  is calculated as follows:

$$fp(x) = \frac{1}{|C|} * \sum_{c_i \in C} \frac{y(c_i)}{n(c_i)}. \quad (3)$$

The values of  $fp$  range from 0 to 1. If every benign node in the network is considered benign by all of its neighbours,  $fp$  is equal to 0 and if all benign nodes are considered malicious by all of its neighbours,  $fp$  equals to 1.

**Objective function 3.** The consumed *memory* ( $mem$ ) in a solution  $x$  is averaged over all benign nodes in the WSN as follows:

$$mem(x) = \frac{1}{|C|} * \sum_{c_i \in C} m(c_i), \quad (4)$$

where  $m(c_i)$  is calculated using formula 1.

The values of  $mem$  range from 0, where the IDS is potentially switched off, to  $8 * p_1 + 16 * p_2$  that is 1200 bytes for our upper bounds of  $p_1 = 50$  and  $p_2 = 50$ .

All three objectives are *minimized*.

## Pareto Front Discussion

The true Pareto front of a *sparse topology* (discussed in the next section) found by exhaustive search is shown in Fig. 1. The goal of MOEA is to find IDS configurations that are close to the points of the true Pareto front as much as possible. In Fig. 1 (a), the view of the whole objective space is shown from the perspective of  $mem$ ,  $fp$  and  $fn$ . Fig. 1 (b) depicts the trade-off between  $fp$  and  $fn$ , where the resulting values depend on the *detection threshold* of the IDS (parameter  $p_4$ ). Fig. 1 (c) shows a slight increase of  $fp$  (see scale) with higher number of *monitored nodes* (parameter  $p_1$  influencing  $mem$ ). The  $fp$  increase is caused by the fact that an IDS monitors a higher number of legitimate neighbours, each of which may be falsely considered malicious. Finally, Fig. 1 (d) shows a rapid decrease of  $fn$  with a higher number of *monitored nodes* (parameter  $p_1$ ) that is caused by the fact that a higher number of neighbours (and hence malicious nodes) is monitored (detected).

Figure 1: Optimal solutions on the Pareto front in our *objective space*.

### Comparison Methodology

In this section, we present a methodology that we used to compare NSGA-II and SPEA2 using multiple settings. We tried different configurations (see Table 2) of the algorithms on our problem and compare the outcome according to four metrics that are defined further in the text.

#### Evolution Parameters

The evolutionary algorithms have several parameters influencing the evolution process. The setting of the parameters is presented in this subsection.

**Initial population.** The initial population consists of randomly generated individuals (more specifically, the values of the IDS parameters are generated randomly within the predefined range of values).

**Population size.** The size of the population  $PopSize$  is set to following values:  $PopSize \in \{50, 100, 200\}$ .

**Crossover.** The multi-point crossover operation is applied with the probability  $PCross \in \{0.01, 0.1, 0.25, 0.5\}$ .

**Mutation.** The mutation operation is applied with probability  $PMut \in \{0.01, 0.1, 0.25, 0.5\}$  to every parameter  $p_1, \dots, p_4$  separately. When applying mutation, the parameter is changed randomly within an interval around the previous value of that parameter covering 10% of the overall parameter range (5% in both directions).

**Number of generations.** The number of generations  $NGen$  is set to  $NGen = 200$ .

Having the setting of the evolutionary parameters specified above, the IDS parameters were optimized with

$|PopSize| * |PCross| * |PMut| = 3 * 4 * 4 = 48$  different settings of both algorithms NSGA-II and SPEA2.

#### Metrics

Following notations are used to define metrics for the comparison of the algorithms:

**Notation 7** The set  $P$  is a set of all vectors (solutions) on the true Pareto front,  $\mathbf{p} \in P$  is a Pareto optimal vector and  $p = |P|$  is a size of the set  $P$ .

**Notation 8** The set  $N$  is a set of all vectors (solutions) found by the evolution,  $\mathbf{n} \in N$  is a non-dominated vector found by the evolution and  $n = |N|$  is a size of the set  $N$ .

Since we calculate the Euclidean distance between the solutions in the objective space in Metric 2 and Metric 3 defined below, we “normalize” the amount of the consumed memory in the following way:

**Notation 9**  $memn(x) = mem(x)/1200$ , where 1200 is the maximal amount of consumed memory in bytes and the range of the function  $memn$  is  $< 0, 1 >$ .

The MOEAs maintain an *archive* of the found non-dominated solutions. Two following aspects are expected of the solutions kept in the archive:

- *Convergence* – The approximation of the Pareto front should converge to the true Pareto front with new generations.
- *Diversification* – The found solutions should be uniformly distributed in the objective space in ideal case.

To be able to measure the effectiveness of the differently set MOEAs with respect to the aforementioned performance aspects, we use the following metrics to measure *convergence*:

**Metric 1.** The value of  $M_1$  is the number  $nd$  of non-dominated solutions  $\mathbf{nd} \in P$  found by the MOEA. The complexity of the calculation of this metric is  $O(nd * p)$ . This metric is used to measure *convergence*.

**Metric 2.** The value of  $M_2$  (*generational distance metric*) is the average of Euclidean distances from all found solutions  $\mathbf{n} \in N$  to the nearest solution  $\mathbf{p} \in P$  on the true Pareto front (Deb et al., 2002). This metric is also used to measure *convergence*. Having  $n$  solutions and  $p$  Pareto dominant solutions, the complexity of the calculation of this metric is  $O(n * p)$ .

Several metrics can be used to measure *diversification*, yet with an assumption that it is straightforward to find a neighbouring solution in the objective space. However, the definition of the neighbouring solution is easy for a two-dimensional objective space, but much more complicated for three- or more-dimensional objective spaces. In our case,

we have three objective functions. Thus, we use the following metric for diversification specified by Schott in (Schott, 1995) as *Spacing metric*. Note that the calculation of this metric does not require the set of the true Pareto front  $P$  found in the exhaustive search:

**Metric 3.** *Diversification* is measured using  $M_3$  as follows:  $M_3 = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (\bar{d} - d_i)^2}$ , where  $d_i = \min_j \{|fn(i) - fn(j)| + |fp(i) - fp(j)| + |memn(i) - memn(j)|\}$  and  $\bar{d}$  is an average of all distances  $d_i, i \in \{1, \dots, n\}$ . If  $M_3 = 0$ , the solutions are spaced equally in the objective space. Having  $n$  solutions, the complexity of the calculation of this metric is  $O(n^2)$ .

We also calculate the time requirements of the MOEA, where the runtime of one simulation needed to evaluate a single individual in a population is the most time consuming element (around 8 minutes for our *Sparse topology* discussed farther). Note that the overall time is also dependent on the number of available CPUs:

**Metric 4.**  $M_4$  is the number of simulations needed in the whole evolution process.

We compare the number of individual evaluations during MOEA with number of evaluations needed for the exhaustive search for each of the experiments. In the exhaustive search, we evaluated 25,000,000 IDS configurations using our BOINC distributed computation platform.

### Our Test Case

We evaluated the performance of the NSGA-II and SPEA2 in two following different simulation scenarios consisting of 250 sensor nodes and 1 BS in 1) *sparse* and 2) *dense* topology. In both topologies, the goal of the IDSs was to detect five malicious nodes. Their placement can be found in (Stehlik et al., 2013).

- **Sparse topology** (Topology #1) – The sensor nodes are placed in the area of 200 x 200 m. The average area for one node is  $160 \text{ m}^2$ , i.e., the distance between two nearest neighbours is 12.65 m in average.
- **Dense topology** (Topology #2) – The sensor nodes are placed in the area of 100 x 100 m. The average area for one node is  $40 \text{ m}^2$ , i.e., the distance between two nearest neighbours is 6.33 m in average.

## Results and Discussion

In this section, we discuss the results of NSGA-II and SPEA2 configured in different ways. Evolutionary algorithm is a *stochastic* process – it means that multiple runs should be done for each configuration to get average behaviour of the algorithm. We ran the evolution 10 times for all the settings and we provide the *average* value  $Avg_x$  and

*standard deviation*  $\sigma_x$  for every metric  $M_x$  computed from results obtained for all ten evolution runs. Since we are limited in space, detailed results can be found in (Stehlik et al., 2013), as well as IDS settings of Pareto optimal solutions.

Table 2 shows how the results of the metrics using different set of evolution parameters are numbered in the charts presented in this section. MOEA settings used for sets 1, ..., 16 (*PopSize* = 50) are presented in the Table 2. Sets No. 17-32 and 33-48 have analogous MOEA settings for *PopSize* = 100 and *PopSize* = 200, respectively.

No.	1	2	3	4	5	6	7	8
<i>PCross</i>	0.01	0.01	0.01	0.01	0.1	0.1	0.1	0.1
<i>PMut</i>	0.01	0.1	0.25	0.5	0.01	0.1	0.25	0.5

No.	9	10	11	12	13	14	15	16
<i>PCross</i>	0.25	0.25	0.25	0.25	0.5	0.5	0.5	0.5
<i>PMut</i>	0.01	0.1	0.25	0.5	0.01	0.1	0.25	0.5

Table 2: The MOEA parameters settings for *PopSize* = 50.

### Sparse Topology

The lowest number of neighbours is characteristic for the *sparse topology*. A node  $b_j \in C \cup A$  has 41 neighbours in average. Hence, a lower amount of memory is needed to achieve IDS accuracy comparable to that in *dense topology*.

**Exhaustive Search** The true Pareto front obtained for the *sparse topology* is shown in Fig. 1. The results of the exhaustive search showed that 2,340 IDS configurations (out of 25,000,000) are Pareto dominant resulting in 996 unique solutions in the objective space (some IDS configurations have same results).

**Convergence** Fig. 2 shows solutions found by a single run of the MOEAs for set No. 45 that provided good results in a relatively short time. We consider a case where NSGA-II found 121 mutually non-dominated solutions, where 29 were Pareto optimal. SPEA2 found 80 mutually non-dominated solutions, where 20 were Pareto optimal. Objective space for evolution set No. 48, where solutions found by SPEA2 are spread better, can be found in (Stehlik et al., 2013).

In Fig. 3 (a) and (b), the impact of the evolution parameters on the convergence is shown. NSGA-II found more solutions on the Pareto front (metric  $M_1$ ) in most cases than SPEA2. Nevertheless, SPEA2 has better results measured by metric  $M_2$ . This is caused by NSGA-II solutions that have redundant amount of consumed memory remained in the population archive (e.g., solutions on the right-top corner in Fig. 2). These solutions were not dominated by other solutions with lower *fn*, *fp* and *mem* during the evolution.

Figure 2: Solutions found by MOEAs for sparse topology using evolution parameters No. 45.

Figure 3: Results of metrics for sparse topology.

We found out that higher crossover probability has a higher impact on the speed of convergence than mutation probability from the perspective of metric  $M_2$ . See quartets in Fig. 3 (b). It is possible to obtain good results with high crossover probability and low mutation probability, but much more difficult if the crossover probability is very low. However, both parameters, as well as the population size, have a positive impact on the convergence.

**Diversification** There is a difference between *diversification* of NSGA-II and SPEA2 for our problem. Fig. 3 (c) suggests that the solutions are spread better using SPEA2. However, checking the objective space (Fig. 2) provides additional information on spreading of the solutions within the whole objective space that is better for NSGA-II. Note that SPEA2 found better spread solutions if mutation probability is higher.

Figure 4: Results of metrics for dense topology.

**Evaluations** The number of simulations needed to evaluate the individuals in the population using a simulator are depicted in Fig. 3 (d). All MOEA parameters influence the number of evaluations, but  $PMut$  and  $PopSize$  have a higher impact than  $PCross$  (see, e.g., sets No. 36, 40, 44 and 48 with different values of  $PCross$  vs. sets 33 – 36 with different values of  $PMut$ ).

Note that, e.g., set No. 45 required only 3,497 simulations for NSGA-II and 2,101 simulations for SPEA2 in average. 24.8 and 14.4 Pareto dominant solutions were found for NSGA-II and SPEA2, respectively. Since the solutions cover different parts of the Pareto front (especially for NSGA-II), the evolution is much more efficient than evaluation of 25,000,000 configurations in case of exhaustive search.

### Dense Topology

In the *dense topology*, a node  $b_j \in C \cup A$  has 127 neighbours in average.

**Exhaustive Search** The true Pareto front obtained for the *sparse topology* can be found in (Stehlik et al., 2013). The results of the exhaustive search showed that 20,072 IDS configurations (out of 25,000,000) are Pareto dominant resulting in 2,219 unique solutions in the objective space.

**Convergence, diversification and evaluations** Results for evolution sets No. 45 and 48 can be found in (Stehlik et al., 2013). Similarly to the *sparse topology*, optimized solutions are spread better for SPEA2 in case of evolution set No. 48. The experiment showed similar characteristics of performance based on evolution settings as for *sparse topology*. The results of all performance metrics are shown in Fig. 4.

## Conclusion

In this work, we extended our *optimization framework* to utilize MOEAs in the process of IDS parametrization. The multi-objective approach is beneficial since it provides the network operator with a set of optimized solutions. He/she can select a solution according to the purpose of the WSN and change the IDS settings according to current needs. We showed that the knowledge of the Pareto optimal solutions is advantageous. However, the computation using exhaustive search is extremely time-demanding. MOEAs proved to be a good compromise between the quality of Pareto front approximation and the optimization time.

We compared two widely used MOEAs: NSGA-II and SPEA2. The results suggest that NSGA-II might be better for our needs. However, one should be careful with a definite conclusion. Various metrics, as well as visualization of the objective space, provide different views of the algorithm performance.

We also focused on the impact of MOEA parameters on the speed of convergence, number of evaluations and quality of Pareto front approximations. Higher population size provides better results at the cost of higher number of evaluations. We found out that a higher crossover probability does not increase the number of evaluations as much as a higher mutation probability and has a better impact on the quality of Pareto front approximations.

In the future, we plan to optimize techniques to detect other attacks than selective forwarding. We would also like to extend the optimization framework to design robust solutions in complex environments. Finally, we plan to adapt and use our framework for the optimization of a whole network stack.

## Acknowledgments

We would like to thank Lukas Sekanina for his invaluable advice. This work was supported by the GAP202/11/0422 project of the Czech Science Foundation.

## Abstract

This paper addresses the problem of generating natural behavior of autonomous virtual characters. Inspired by the fields of Embodied and Enactive Artificial Intelligence, we postulate that natural behavior is the result of a coupling between the agent and the world where it lives, which leads to a coherence between its actions and its surroundings. In this work, we present the tools that we have been using to study that idea: a controller based on a plastic neuromodulated neural network, which is capable of molding itself to received stimuli; and a simple novel method for genetic encoding of artificial neural networks. We show the capabilities of the controller in generating interesting foraging behavior of an autonomous virtual robot, and discuss the advantages of its emergent characteristics when compared with traditional approaches.

## Introduction

An important requirement for a user's sense of immersion in a virtual world is the way things move in the environment, so that it can be truly perceived as the real world. Zahorik and Jenison (Zahorik and Jenison (1998)) put it in this way: "When the environmental response is perceived as lawful, that is, commensurate with the response that would be made by the real-world environment in which our perceptual systems have evolved, then the action is said to successfully support our expectations".

The term "lawful" is appropriate to describe the behavior of inanimate elements that follow the physical laws. However, what is taken to be natural for the living elements, seems to be the opposite of simply following rules. The behavior of autonomous virtual characters plays an important role in virtual reality environments and obtaining such behavior in a natural and realistic way is still an open problem. We argue that unnatural behaviors are typically obtained by a lack of connection between the character and the world around it in rule-based implementations.

In this paper we propose:

- A controller that is capable of adapting itself to the character's bodily constitution and to the characteristics of the

environment, causing the emergence of appropriate foraging behavior in an autonomous virtual robot; and

- A simple novel method for genetic encoding of artificial neural networks (ANNs).

In the next section, we discuss the traditional methods used by the virtual reality community in generating behaviors of virtual characters, analyze the characteristics of those behaviors, and present some thoughts on the proposition that an emergentist approach could help to overcome the limitations resulting from approaches that attempt to explicitly model the cognitive abilities of the agents.

We also describe the tools that have been employed for studying the emergence of foraging behavior:

- A neuromodulated network for processing sensorial information and generating signals for motor action, which is capable of local modulation of synaptic plasticity; and
- A genetic algorithm (GA) evolution mechanism, which selects the most adapted neural networks.

We show our results with a simulated Khepera-like robot, equipped with sensors that input the robot's distance to a fruit or poison to the neural network. The robot's motor skills are moving forward and backward, and turning left or right. The experiments show that the robot was capable to learn how to make proper use of its sensors and motors in order to catch fruit and avoid poison, displaying a complex navigation control behavior. In conclusion, we present final discussions about the obtained results and future works on our study about natural behaviors of virtual characters.

## Behavior Generation of Virtual Characters

Our basic assumption is that the behavior of a virtual character can only be called realistic if it reflects the details of the agent's bodily constitution, and has a close and logical association with the events taking place in the virtual environment. Accordingly, this work supports the idea that the realistic behavior should be obtained as the result of a permanent and intimate dialogue between the agent and its en-

vironment. This position is motivated by the Embodied (Anderson (2003)) and Enactive (Froese and Ziemke (2009)) approaches to AI, where intelligence is perceived as something that emerges from a close interaction among all the components involved in the cognitive phenomenon.

Here, we have a clear contrast with the classical strategies for the simulation of behavior, which concentrate their efforts on embedding the relevant aspects of reality within the agent's mind (in the form of models and "knowledge"), and internally calculating what appropriate action should be performed in a given situation (Shao and Terzopoulos (2007); García-Rojas et al. (2007); Gutierrez et al. (2007); Whiting et al. (2010); Orozco et al. (2011)). The main drawback of that approach is the great difficulty of maintaining a complete and updated description of the relevant aspects of reality, especially in the case of highly dynamical environments. So, a typical result is the strong attachment of the agent's behavior to the rules and facts stored in its mind, rather than an involvement and interaction with what is really happening in its surroundings. That generates a feeling of detachment, which we sometimes classify as robotic behavior.

The diagram in Figure 1a illustrates the traditional approach for behavior generation. That approach subdivides the problem into a cognitive level and a motor level, modeling each of those parts separately. In that view, the cognitive level works as a calculator of abstract facts, i.e., the manipulation of symbols already interpreted by the programmer, which correspond to a high-level perception of the world. That calculation should provide the correct (or desired) command to the motor level, which has a built-in set of behaviors fully described, such as walking, sitting or standing in line. The so called reactive agents are typically implemented based on this two-level modelling. To mitigate the problems inherent with this approach, some works (Pina et al. (2006); Schneider and Rosa (2009)) attempt to use techniques of machine learning to automate the process of behavior selection.

To avoid the detachment problem, we propose that the behavior of autonomous virtual characters should be generated through a methodology of emergence. More specifically, we suggest that efforts should migrate from detailed internal representations of reality and explicit descriptions of behavior, to the construction of appropriate conditions that would induce the coupling of the structure and dynamics of mind, body and environment, resulting in the emergence of intelligent behavior. In this way, we expect to obtain the degree of coherence between agent and environment which is required for natural behavior.

The notion of an emergent property of a system refers to a global characteristic of the system that cannot be found in any of its parts (Klaus and Mainzer (2009)). Accordingly, by emergent behavior we mean that the characteristics of the behavior that emerges are not described or encoded in any of the components that define the system: the logic of the controller, the anatomy of the body, or the environment con-

figuration. In fact, the behavior must result from the combination of the properties of all those components.

The works based on the emergentist approach (Sims (1994); Chaumont et al. (2007); Nogueira et al. (2008); Panzoli et al. (2010); Palmer and Chou (2012)) use two basic elements to support the emergence of high-level behaviors: the uninterpreted signals received from the environment, and the elementary movements performed by the body parts. The internal dynamics of the body and mind of the agent should then modulate this information in order to establish a sensorimotor flow that coordinates the low-level movements in order to produce the emergence of high-level behavior. This idea is illustrated in Figure 1b. The key aspect that makes this process possible is that some components have a degree of plasticity, so that their structures and internal dynamics can be modified over time, in response to interactions with other components of the system, in an evolutionary dynamics.

Figure 1: Approaches to behavior generation. The two-level modeling (a), and the emergentist approach (b).

Emergence phenomena tend to produce very specific configurations which are sensitive to small changes in the elements that constitute the system. This observation is consistent with the fact that animals of different species sometimes solve the same problem in radically different ways. This is illustrated by the great diversity of behaviors of locomotion, hunting, breeding, etc. that we find in nature. If the assumption that emergent phenomena are an important aspect of behavior, that would explain, in part, why the problem of realistic simulation has resisted for so long to approaches based on traditional AI techniques: the details of the situation are what determine the behavior of the agent. But these details are precisely what is left out in the process of abstraction inherent to representationalism. In other words, the attempt to simulate the behavior of an agent based solely on a high-level description of the situation in terms of goals and motivations of the agent, complex actions that the body can perform, and qualities of objects and features of the environment, leads almost inevitably to mechanical and unnatural behavior.

## The Controller

Here, we present a controller for generating behaviors of virtual characters based on emergence. As we argued, to achieve the emergence of behavior, an essential factor is the

generation of a dynamics which is capable of modifying and adapting the controller to the body of the character and to the environment around it. Aiming at this goal, we chose to evolve a plastic neuromodulated neural network to generate the signals that control the motors of a virtual robot based on its sensory information. The neuromodulatory property brings lifetime adaptation to the network, while a genetic algorithm evolves the network providing adaptation throughout the generations.

## The Neural Network

The neural network that we used is essentially a Continuous Time Recurrent Neural Network (CTRNN), whose neurons are modeled in the following general form (Beer (1995)):

$$\frac{dy_i}{dt} = \frac{1}{\tau_i}(-y_i + \sum_{j=1}^n w_{ji}f(s_j) + I_i) \quad (1)$$

where  $t$  is time,  $y_i$  and  $\tau_i$  are, respectively, the internal state and time constant for each neuron  $i$ ,  $w_{ji}$  is the weight of the  $j$ th input synapse of neuron  $i$ ,  $s_j$  is the state of the neuron linked to the  $j$ th input synapse,  $f()$  is the activation function of a neuron and  $I_i$  represents a constant external input to neuron  $i$ . In this work we used the same  $I$  for all neurons, simulating an external stimulus from a higher center such as the mesencephalic locomotor region of animal brains.

In addition to this standard dynamics, we chose to include a neuromodulatory feature in the neural network. As discussed by Soltoggio et al. (Soltoggio et al. (2007)), the neuromodulation plays an important role in neural substrates from invertebrates to the human brain, and is related to the induction of Late phase - Long Term Potentiation (L-LTP), a phenomenon of permanent growth of the synaptic contact in brain, causing synaptic stability, being a potential candidate for explaining memory functions involving neural wiring and, consequently, learning. Another mechanism of neural wiring related to neuromodulation is the Long Term Depression (LTD), the permanent decrease of the synaptic contact (Soltoggio et al. (2008)).

Soltoggio et al. proposed the use of a model of neuromodulation in T-Maze (Soltoggio et al. (2008)) and in bee foraging behavior (Soltoggio et al. (2007)). We use the same model in our work, in order to study the effects and advantages of such dynamics in the behaviors of our virtual characters. It consists of a CTRNN with two types of neurons: standard neurons, which are the processing units, and modulatory neurons, which are responsible for modulating the changes of weights in the synapses following the Hebbian rule. Figure 2 shows the modulation mechanism.

Equation 1 defines the activities of the standard and modulatory neurons. The signals of both types of neurons are computed according to that equation, with the activation function  $f(x) = \tanh(x/2)$ . However, only the input signals that come from standard neurons, and the weights of

Figure 2: The network processing itself is made only with the standard neurons. The modulatory neuron determines the response of the Hebbian rule, mediating the amount of growth or decreasing of the synaptic weight.

the respective synapses, are considered for the summation in that equation.

The value of modulatory activation  $m$  acting on a neuron  $i$  is computed as follows:

$$m_i = \sum_{j \in Mod} w_{ji} \cdot \tanh(s_j/2) \quad (2)$$

where  $j$  represents all modulatory neurons connected to neuron  $i$ ,  $w_{ji}$  is the weight associated with the synapse that links modulatory neuron  $j$  to neuron  $i$  and  $s_j$  is the internal state of modulatory neuron  $j$ .

Finally, the synapse's weight change is defined by the following equation:

$$\Delta w_{ji} = \tanh(m_i/2) \cdot \eta \cdot [A o_j o_i + B o_j + C o_i + D] \quad (3)$$

where  $\Delta w_{ji}$  is the amount of change in the synapse that links the standard neuron  $j$  to a neuron  $i$ ,  $\eta$  is the learning rate,  $A$ ,  $B$ ,  $C$  and  $D$  are tunable parameters, and  $o_j$  and  $o_i$  are the activation function  $\tanh(x/2)$  applied to internal states of neurons  $j$  and  $i$  respectively. Note that this rule is unstable if the parameters are such that  $\Delta w_{ji}$  is always positive or always negative. To avoid that, we limit the weights of all input synapses of each neuron. Equation 3 differs from the Hebbian rule only on the modulatory term, i.e.,  $\tanh(m_i/2)$ . That is, the modulatory effect changes the learning rate of the Hebbian rule.

The model presented here differs from that of Soltoggio's work in the way we define the input and output neurons. Our work defines some standard neurons as afferent neurons or efferent neurons, which have no internal dynamics. The internal state of an afferent neuron is a sensor value and cannot receive input from other neurons, while an efferent neuron stores the average of the internal states of each neuron connected to it, defining the outputs of the network.

## The Evolutionary Algorithm

**Evolving neural networks** In the literature, we find three main general techniques to evolve neural networks with GA aiming at topology search (Mattiussi and Floreano (2007)): direct encoding, developmental encoding and implicit interaction. In this work, we propose a novel simple method based on the third technique to search appropriate values

to the weights, the time and tuning parameters, the learning rate, the neurons to define as input or output, and the topology of our ANN.

Direct encoding is a straightforward approach, in which the chromosomes describe exactly the graph of the neural network. That requires complex gene and genetic operators specifications oriented to graph evolution, aiming at the maintenance of its consistency, which makes it difficult to simultaneously evolve several characteristics not naturally describable with this type of structure. A well-known algorithm based on direct encoding is the NeuroEvolution of Augmenting Topologies (NEAT) (Stanley and Miikkulainen (2002)).

The developmental encoding genome describes the rules of a developmental process of the network, i.e., the process of constructing and growing the network. This approach resembles genetic programming and allows a compact description of the network. However, it is very difficult to define the genetic operators, and a poor definition can lead to unsatisfactory results in terms of evolution.

Implicit interaction is a biologically inspired technique based on the fact that the interaction between genes in the DNA is the key to the definition of their expressions. The Analog Genetic Encoding (AGE) (Mattiussi and Floreano (2007)) is a well-established encoding based on this idea. The genome is represented as a simple string of characters, allowing the use of traditional genetic operators such as crossover and mutation, while keeping the structure and consistency of the network. Since the encoding we propose is based on AGE, next we describe it in more detail.

In AGE, while neurons are explicitly described in the chromosome, synapses are implicitly defined, since they are formed by the interaction between genes, and not by a gene itself. The genes specify the neurons and their respective terminals, i.e., their inputs and outputs, while interactions between terminals form the synapses. To assemble the synapses, the inputs of all neurons are aligned with the outputs of all neurons and an alignment score is calculated, which indicates the weight of the synapses between the aligned neurons.

Each element of the neural network is encoded in the AGE's chromosomes into substrings called tokens. For example, to encode a neuromodulated network, Soltoggio et al. (Soltoggio et al. (2007)) used the tokens NE to indicate a standard neuron, MO to indicate a modulatory neuron and TE to delimit a terminal sequence.

A terminal sequence is an arbitrary sequence of characters that precede the token TE and defines a neuron's terminal. After a neuron token, all the subsequent characters until a TE token are translated as a neuron's terminal. Each appearance of TE determines a neuron's terminal, and, so, the neuron has as many terminals as the number of TE's appearances after it.

AGE is supposed to accomplish the evolution of any type

of analog network, such as electronic networks, neural networks and genetic regulatory networks. To do that, the alignment score is based on a network-specific interaction map that leads to a complex chromosomal representation. Our proposal focuses on ANNs and specifies the chromosome as a binary array, encoding the parameters of the network in a more straightforward way, using a simpler similarity function, and still maintaining the advantageous properties of AGE's interaction maps (Mattiussi and Floreano (2007)) for ANNs evolution. Such an encoding scheme allows us to easily search augmenting topologies of neural networks composed of different types of devices (neurons).

**The Proposed Genetic Encoding** Our chromosomes are arrays of bits, with each group of 32 bits defining a gene. The first 8 bits (1 byte) of the gene are used to encode an identifier, which indicates the element that the gene represents in the network. The last 24 bits specify a value that indicates a property of the decoded element.

Each individual in the population has two chromosomes: one chromosome stores the global parameters of the neural network, while the other keeps the network itself. The global parameters are the values of the variables in Equation 3 and the external stimulus of the CTRNN (Equation 1). Figure 3 shows the distribution of values in the chromosome.

I	$\eta$	A	B	C	D
---	--------	---	---	---	---

Figure 3: Encoding of the global parameters of the network.

To decode the network chromosome, we have to read each gene and isolate its identifier and value. The 8 bits of the identifier are decoded according to Table 1. The 24 bits that encode the value of a gene are linearly mapped into a floating-point value  $v$  in the range  $[-1, 1]$ , according to the formula:

$$v = \left( \frac{n}{2^{24} - 1} \cdot 2.0 \right) - 1.0 \quad (4)$$

where  $n$  is the unsigned integer encoded in the value bits.

Table 1: Genes' identifiers	
Byte	Meaning
$0 \leq id \leq 38$	Standard Neuron (SN)
$39 \leq id \leq 51$	Modulatory Neuron (MN)
$52 \leq id \leq 255$	Neuronic Terminal (TR)

With the distribution of identifiers shown in Table 1, we have the following probabilities:  $P(SN) = 0.15$ ,  $P(MN) = 0.05$  and  $P(TR) = 0.80$ , assuming a randomly generated chromosome. This distribution was chosen because we want to have more standard neurons, which actually do the signal generation, than modulatory neurons, which only change the plasticity. At the same time, we need

to have more synapses than neurons, and, for this reason, the probability of creating terminals is greater than that of creating a neuron. The probabilities were empirically chosen.

Suppose that the robot we want to control has  $s$  sensors and  $m$  motor outputs. To keep some structure of the neural network in the chromosome, we fix the first  $s$  genes that encode SN to be afferent neurons, while we set the last  $m$  genes that encode SN to be efferent neurons.

The value of a gene (i.e., the last 24 bits) identified as a SN or a MN, encode the time constant  $\tau$  in Equation 1. The exceptions are the afferent neuron, whose value identifies a stimulus parameter, and the efferent neuron, whose value is ignored, since it has no internal dynamics. The stimulus parameter is  $-1$ , if  $v < 0$  or  $1$ , if  $v \geq 0$ , and is multiplied by the sensor signal, generating excitatory or inhibitory sensory signal as input to the neural network.

The genes identified as TR have the value part corresponding to the input or output terminals of the last-read neuron. The first TR read after a neuron's gene is always its input, while the second TR is always its output. Such genes are ignored if no neuron was read before them or the last-read neuron already has its terminals. However, their presence in the chromosome is useful to generate new combinations by the genetic process.

The parsing of a chromosome produces a list of neurons with their respective parameters and terminals that will compose the network. Similar to what is done in AGE, we pair neurons by their terminals to create the synapses arriving at or leaving the neurons. However, instead of using an interaction map, we define the synapses' weights according to a similarity measure. The idea is to use a proximity function, computing a distance value of two numbers based on the Hamming distance between their binary representations, according to equation:

$$w(i, o) = \frac{eb \cdot (i + o)}{nb \cdot 2}, \quad (5)$$

where  $w$  is the weight of a synapse that links an output of value  $o$  with an input of value  $i$ . The symbol  $nb$  indicates the total number of bits that represent the value (24 bits), and  $eb$  is the number of equal bits at the same position between the binary representations of  $i$  and  $o$ . We also defined an existence condition empirically to increase topological diversity: if  $\lfloor eb/4 \rfloor \bmod 3 = 0$  then  $w(i, o) = 0$ .

Equation 5 may be interpreted as: the synapse weight is the average of the input and output parameters weighted according to distance. The occurrence of two terminal parameters with zero equal bits, implies a maximum distance from each other, and, therefore, there is no synapse linking them. The idea of the similarity function is that if the number of equal bits is the maximum possible, then  $nb = eb$ , which implies that the synapse weight is the average of both parameters. Equal parameter values imply a synapse weight with the same value.

In order to understand the decoding process better, take Table 2 as example of an excerpt from a chromosome. Analyzing the identifiers based on Table 1, we have two neurons in the chromosome: an SN on gene G1 with value 15,000,000, and an MN on gene G4 with value 8,500,000. Using Equation 4 with those values, we obtain  $\tau_{SN} = 0.79$  and  $\tau_{MN} = 0.01$ .

Table 2: Sample excerpt from a Network Chromosome

	G1	G2	G3	G4	G5	G6
Identifier	30	120	240	40	125	200
Value	15M	10M	4M	8.5M	11.5M	6M

Genes G2 and G3 are the input and output terminals of SN, while G5 and G6 are the terminals of MN in the same order. From Equation 4, we have the values  $TR_{G2} = 0.19$ ,  $TR_{G3} = -0.52$ ,  $TR_{G5} = 0.37$  and  $TR_{G6} = -0.29$ . Figure 4 illustrates the resulting neural organization.

Figure 4: Neurons decoded from Table 2.

Finally, the synapses' weights of the network are computed with Equation 5 applied to each pair input-output, i.e.:  $w(TR_{G2}, TR_{G3})$ ;  $w(TR_{G2}, TR_{G6})$ ;  $w(TR_{G5}, TR_{G3})$ ;  $w(TR_{G5}, TR_{G6})$ .

Let us compute  $w(TR_{G2}, TR_{G3})$  as an example. The binary representation of those parameters, i.e., the way they are stored in the chromosome, are:

$$\begin{aligned} \text{bin}(0.19) &= \text{bin}(10M) = 100110001001011010000000 \\ \text{bin}(-0.52) &= \text{bin}(4M) = 0011111010000100100000000 \end{aligned}$$

From these representations, we have  $eb = 13$ . Thus, using Equation 5, we would have  $w(0.19, -0.52) = -0.09$ . However, the existence condition,  $\lfloor 13/4 \rfloor = 3$  implies that  $3 \bmod 3 = 0$ , and thus there is no synapse from standard neuron to itself. Similarly computing the other weights, we will have only one synapse, from MN to SN, with  $w(TR_{G2}, TR_{G6}) = -0.03$ . Figure 5 shows the fragment of the network decoded from Table 2.

Figure 5: Network decoded from Table 2.

**The Simulation of Evolution** To evolve the individuals, we simply apply the canonical genetic algorithm. The relative chromosomes of the individuals are paired and the duplication, crossover and mutation operators are applied. Note that, since a chromosome is simply an array of bits,

crossover can break a gene, causing a new gene to appear. The simple mutation of a single bit also can lead to the appearing of a new gene.

Each individual is decoded and made alive for controlling a virtual robot. The robot has an amount of energy that is reduced proportionally to the strength of the generated signals. The evaluation function we used for the emergence of foraging behavior was the number of collected food multiplied by the robot's lifespan.

## Case Study

### Description of Experiment

To evaluate the proposed controller, we put it to control a Khepera-like virtual robot in a foraging task. The environment consists of randomly distributed fruits and poisons. The simulation was developed with the *Irrlicht 3D Engine*<sup>1</sup>, with physics provided by the *Bullet Physics Engine*<sup>2</sup>.

The robot is shown in Figure 6. It has a cylindrical body with a black box that plays the roles of eye and mouth. The robot "eats" a fruit or a poison if that box touches them.

Figure 6: The robot. (a) Robot in the environment. The black box is its eye and mouth. (b) The three sensors distributed in the eye and their fields of sense. We used 20° Field Of Sense (FOS). The maximum sensing distance is six times the robot's diameter.

The neural network is connected with the body and the environment receiving as input the signals of the robot's sensors. There are three sensors aligned side by side at the extent of the eye (Figure 6b), each one able to catch the normalized distance  $([0, 1])$  to the nearest fruit and poison inside its FOS. This implies the generation of six values. There is also a proprioceptive sense of energy, that enables the robot to sense its level of energy spending, which ranges from 0 (the robot is fully energized) to 1 (the robot is totally exhausted). In this way, the strength of the signal allows the robot to perceive when its energy is finishing. This ANN then needs seven afferent neurons.

The robot has two motors, one to move forward or backward and another to make left or right turns, each one controlled by one efferent neuron. When the first motor receives a positive value, the robot moves forward and if it receives

a negative value, the robot moves backward. With a positive value, the second motor makes the robot turn right, otherwise it causes the robot to turn left. The robot's energy is reduced every simulation step according to Equation 6, where  $o_1$  and  $o_2$  are the output of the two efferent neurons of the ANN. The constant value 10 is used in order to avoid the evolution of stationary robots.

$$C = (|100 * o_1| + |100 * o_2|)^2 + 10. \quad (6)$$

A robot starts with 50,000 energy units (eu). This value increases 10,000eu whenever a good fruit is eaten (up to a maximum value of 50,000eu) and decreases in two situations: (1) when the robot is alive, its energy is continuously decreasing in proportion to the applied motor signals, (2) whenever the robot eats a poisonous fruit, its energy is reduced to 10,000eu. In the second situation, if the robot's energy level is less than or equal to 10,000eu, the energy is zeroed. If the energy is exhausted, the robot dies.

Each controller decoded from the chromosomes of an individual is assigned the control of a robot, one at a time. Each trial begins at the same position, and the fruits and poisons are always randomly redistributed to prevent the GA from "memorizing" the positions. A trial ends when the robot's energy is exhausted. The GA randomly generates the first population. The following parameters were used:

- Population size: 100 individuals
- Network chromosome size: 100 genes (3200 bits)
- Type of crossover: Monopoint (one break point)
- Crossover probability: 60%
- Mutation probability (per bit): 0.1%

## Results

Due to space constraints, we will focus on the analysis of type and quality of the generated behaviors and we will not show the measurement data and comparisons of the several runs we made. However, in all executions we made, the same behavioral result was obtained, except for the neuro-modulatory action, that have been developed in rare cases, as we will discuss later. The plots shown in this section represent the typical results of our experiments.

The GA successfully evolved the neural network to control the robot in the foraging task. Figure 7 shows the evolution of the evaluation averages of all the individuals per generation.

The robot successfully acquired the behavior of catching good fruits only, while avoiding the poisonous fruits, as shown in Figure 8a. Note that, although the evaluation function of the genetic algorithm explicitly selects those individuals that collect the greater number of fruits, there is no direct information about poisons. However, we can observe

<sup>1</sup><http://irrlicht.sourceforge.net/>

<sup>2</sup><http://bulletphysics.org/>

Figure 7: Evolution of the evaluation averages of the populations.

the behavior of moving away from the poisonous fruits (Figure 8b), as a consequence of the fact that individuals who eat poisons may “die” sooner.

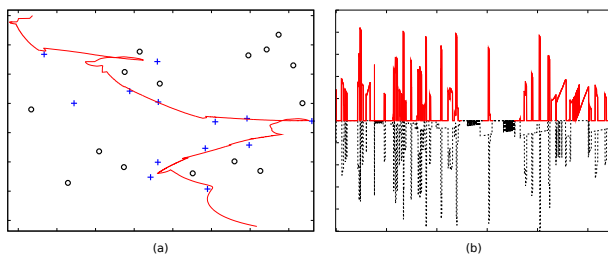

Figure 8: Robot Behavior. (a) The line represents the robot's path, starting at (0,0). Note that its path passes through the fruits (+) while deviates from poisons (o). The line is not always touching the fruits because the graph is showing the center of the objects and, in the simulation, the eye's mesh only needs to touch the fruit's mesh. (b) Motor and poison sensor activities. Note that when a poison is sensed (positive values of solid line), there is a peak of negative signal on motor activity (dotted line), which leads to a backward movement.

An important characteristic to point out about the robot's behavior is how the high level foraging behavior is performed with low level behaviors of direction adjustment. One sensor of the eye alone cannot determine the direction to follow in order to catch the sensed fruit, since it only captures the distance to the fruit. Therefore, the robot needs to change its position to be able to use the three sensors to find out the missing information. This behavior is shown in Figure 9, where we can see the robot turning left to use the right side of a sensor's FOS to follow the fruit. Since the three sensors are slightly displaced with respect to one another, when a fruit leaves the FOS of a sensor, it is possible to determine to what side an adjustment of direction needs to be made. (Figure 6b).

Regarding the modulatory activity, one particular controller evolved with modulatory neurons. With this action, the robot exhibited two ways of search. A local rotation, searching for near food and, when no fruit was caught, it

Figure 9: Direction adjustment behavior. Note that, to catch the fruit, the robot approaches it using the right side of the FOS, instead of the FOS's center. The top frames show the moment that it senses the fruit and then turns left. The bottom frames show the robot catching the fruit following its “side sensing”.

gradually increased its rotation radius, until it found a fruit, and then passed to the local search again. Figure 10 shows the joint activity of the modulatory neuron, stimulated with the energy sense (signal continuously increasing while no food is collected), and the changing of the motor activity.

Figure 10: Motor activity (dotted line), energy sense signal (dashed line) and modulation activity (solid line). Note that these three activities are synchronized. When the robot catches a fruit (decrease in dashed line), it searches another one locally (decrease in dotted line). If no fruit is eaten, it gradually increases the search radius (increase in solid and dotted lines).

## Conclusion

We described a controller for behavior generation of autonomous virtual characters. We argue that natural behaviors can emerge if the behavior controllers are designed properly, taking into account emergence principles. Such a controller must be capable of adapting itself to the body and to the environment. Thus, it needs to be able of modify itself in contact with the world.

The controller uses neuromodulation for changing its dynamics on the fly, while adapted throughout the generations by the genetic algorithm. In animal brains, the neuromodulators are directly related to memory functions and indirectly to learning. In our experiment, they allowed modifications in behaviors patterns according to environmental changes.

We also presented a simple novel way of genetic encoding ANNs, describing simple arrays evolvable with a canonical genetic algorithm. Those arrays are able to evolve neural networks with growing topologies, and, at the same time, is possible to evolve multiple characteristics of an agent.

We showed the capabilities of our controller through an application involving the foraging behavior of a virtual robot. The robot was able to learn how to use its own movements to compensate for the insufficiency of sensory data in order to accomplish the objective of catching fruits, showing a complex foraging behavior consisting of minor position corrections toward the goal. It is worthwhile to point out that when the plasticity of the controller was increased with modulatory actions, more elaborate strategies have emerged.

The results of our experiments show that the emergentist approach is indeed capable of producing the intimate coupling between agent and environment required for natural behavior. This fact is clearly illustrated by the strategy developed by the virtual agent to compensate for its primitive visual sensory apparatus, showing a high level behavior composed of minimal movements extremely connected with the conditions of the world, rather than a simple and straight “follow the fruit” behavior.

On the other hand, the simulations also show that the type of behaviors which we were able to obtain are relatively simple and, at this point of the investigation, it is not clear how to incrementally increase the complexity of the system in an emergent way. However, the traditional techniques can produce behaviors with arbitrary complexity, by using more detailed models and facts about reality, but paying the price of some level of detachment with respect to the environment. So, a natural question is whether it is possible to combine ideas of the traditional and emergent approaches to obtain the advantages of both sides.

## Abstract

Massively Multi-player Online Role-Playing Games and Massively Multiplayer Online games are complex and costly system from both a game design and a technical point of view. Among their many issues, in this paper we tackle the problem of incrementing players thrill by supplying them plenty of freshly produced, unpredictable monsters. To achieve this goal we have designed, developed and tested GOLEM, a genetic-based approach to the evolution of new species of monsters for video games.

## 1. Introduction

In Massively Multi-player Online Role-Playing Games (MMORPGs) and in Massively Multiplayer Online games (MMOs) players interact among them in an online, persistent, and shared virtual world. This game genre has gained success and diffusion especially thanks to the prosperity of Blizzard's World of Warcraft (WoW) (Taylor, 2006). The huge amount of people that interact on an ongoing basis (e.g., more than 10 million in WoW) in a shared environment raises questions for game designers and computer scientists that have scarcely been investigated until now, but that could nonetheless affect the success and survival of a specific game.

Beside the issues related to the game mechanics and the service supply, there is a number of other – only apparently – minor, “tricky” features that could, nonetheless, impact deeply on players' satisfaction with the game (see e.g., Bartle, 2003; Maggiorini et al., 2012a, 2012b). Among these neglected issues, we can enlist several characteristics that are intrinsic to the paths players have to follow to raise the “level” of their characters and that could rise problems of players' loyalty. In particular, to explore the in-game world, complete quests, and gain “experience points”, players are often confronted with different types of monsters (also called “mobs”, which stands for “mobiles”), which they are supposed to slay. In spite of the fact that a game world can contain hundreds of different species of monsters, after spending a certain amount of time playing, players become well aware of the characteristics presented by each specie and its related hazard. In the long run, this knowledge has the drawback of generating a certain amount of boredom in players, which lose the thrill of braving unfamiliar dangers (Koster, 2004).

In this work, we tackle this issue by proposing GOLEM – Generator Of Life Embedded into MMOs: an algorithm aimed at increasing variety and unpredictability among mobs in MMOs, by means of an approach rooted into Genetic Algorithms (GAs). The main idea is to represent each monster

specie in the population present in the in-game world through its genome, and to generate new species by recombining their chromosomes in a way quite similar to what happens in the natural world. This implies also taking into account aspects like the actual possibility for a mob to survive the habitat in which it was born (e.g., a marine-like animal with fins will unlikely survive in a desert), providing an estimate of the population growth (in order to avoid overpopulation), some means to contain the mobs numerosity when needed, etc. Nonetheless, our aim is not to recreate a complex ecosystem, since this will go far beyond the scopes of a generator of monsters for a video game, whose main goal should simply be to increase the players' fun.

The paper is organized as follows: the following Section 2 briefly analyses related works, from both the academy and the industry, while Section 3 recalls the fundamental concepts related to Genetic Algorithms (GAs). The subsequent Section 4 summarizes how we have designed the chromosomes to describe the most diffused fantasy monsters. Section 5 concentrates on the issues related to managing a population of evolving monsters through several generations. Sections 6 and 7 focus, respectively, on the implementation of the GOLEM algorithm and on some perspective results derived from several tests. Finally, Section 8 draws conclusions and delineates major future developments.

## 2. Related works (in video games)

Although scholarly literature on the applications of GAs and Genetic Programming (GP) in video games is quite huge and multi-faceted, in our knowledge, until now it has focused on scopes different from creating diversity among mobs. In particular, the major part of recent works has tackled either the use of GAs to generate or evolve the environment (i.e. the in-game world or game levels), or the evolution of agents (the so-called “bots”) behavior in order to produce more challenging opponents to the players.

In the first category we can enlist, e.g., the work of (Frade et al., 2012), which develops a GP-based procedural content technique to generate procedural terrains that do not require parameterization. Taking a different perspective, (Halim & Raif Baig, 2011) propose a set of metrics for measuring entertainment in video games and then use evolutionary algorithms to generate games using the proposed entertainment metrics as the fitness function. (Mourato et al., 2011) propose an approach rooted into GAs to generate automatically levels for a video game. The only work

suggesting the use of GAs in MMORPGs – to the best of our knowledge – is (de Carvalho et al., 2010), which proposes to use GAs for managing the dynamics of geophysics events, asserting that specific events will occur only in areas where they are prone to. The work of (Frade et al., 2010) uses GP to evolve automatically Terrain Programs, which are able to generate terrains procedurally, for a set of desired accessibility parameters. Finally yet importantly (Sorenson & Pasquier, 2010) developed a genetic encoding technique specific to level design used to generate game levels.

In the second category, we enlist works focused on evolving bots' behavior. For example, (Mora et al., 2012) focus on an evolutionary algorithm designed for evolving the decision engine of a program that plays Planet Wars, a game requiring the bot to deal with multiple target, while achieving a certain degree of adaptability in order to defeat different opponents in different scenarios. (Esparcia-Alcázar & Jaroslav, 2012) focus their attention on the problem of estimating the fitness value of individuals in an evolutionary algorithm while containing time and costs. In the field of racing video games, (Onieva et al., 2012) developed a driving system, whose controller for adapting the speed and direction of the vehicle to the track's shape is optimized by means of a GA. The work of (Inführ & Raidl, 2012) showed how GP could be used to create game playing strategies for 2-AntWars, a deterministic turn-based two-player game with local information. (Barros et al., 2011) used GAs to develop a convincing artificial opponent for chess. (Benbassat & Sipper, 2011) apply GP to zero-sum, deterministic, full-knowledge board games. (Alhejali & Lucas, 2010) used GP to evolve a variety of reactive agents for a simulated version of Ms. Pac-Man. The work presented by (Hong & Zhen Liu, 2010) presents a GA based-Evolvable Motivation Model for bots. Both the works of (Mora et al., 2010a) and (Mora et al., 2010b) focus on the adoption of GAs and GP techniques to evolve bots' behavior in Unreal. Last but not least, (Wong & Fang, 2012) study the applications of neural network and GAs techniques for building controllers for automatic players.

## 2.2 GAs and commercial video games

The use of GAs in commercial video game is still quite limited, at least as far as developers disclose it. The three major titles whose gameplay relates heavily on evolution are *Creatures* – released in its first version by Millennium Interactive in 1996 (Fig. 1), *Spore* – released by Maxis in 2008 (Fig. 2), and *GAR: Galactic Arms Race* – released by Evolutionary Games in 2010 (Fig. 3). None among them uses GAs in a way similar to that envisaged by the present work. In particular, *Creatures* only seems to use chromosome to generate minor variations (e.g. skin colour) in the different generations of Norms (the fictional creatures populating the game world), while the evolution of the specie is based mainly on learning and reasoning algorithms. *Spore* exploits GAs to produce automatically animations for the species created by the players, and uses extensively procedural generation for “evolving” content pre-made by developers. Nonetheless, the game main focus is on the evolution of a single user-created specie. *Galactic Arms Race* exploits NEAT – NeuroEvolution of Augmenting Topologies algorithms to develop spaceships' weapons accordingly to the player's play style.

## 3. Genetic Algorithms

Genetic Algorithms (GAs) are a particular class of algorithms applied to solve many classes of problems, mainly belonging to the Artificial Intelligence (AI) field, but – more in general – they are useful in many optimization problems and in heuristic search processes. They have been inspired by Darwin's evolution theory: the chromosomes of a set of individuals represent a population, and a new generation in the population is produced by recombining, according to specific rules, the genetic material. For each generation, an ad hoc *fitness*

function selects the most “suitable” parents and iterate the reproduction process on them. To produce “children” the algorithm operates genetic recombination techniques (*crossover*) and *mutations* – similarly to what happens in the natural world – on chromosomes represented by bit sequences. Once the new generation has been created, the algorithm verifies whether the population registers any improvement in any relevant feature. If yes, parents will be discarded and their sons will substitute them in the reproduction process. Generally, these steps will be iterated until some optimal solution is reached (Mitchell, 1998; Mode & Sleeman, 2012; Koza, 1998).

### 3.1 Crossover

GAs use *crossover* to mix the genes of the two parents. Crossover can be achieved by different approaches:

1. *Single point crossover*: the chromosome is split into two parts in a randomly selected point. The chromosome describing the offspring is composed by the first section of the first parent chromosome and by the second part of the second parent chromosome. A second offspring will inherit the remaining two parts;
2. *Two points crossover*: the chromosome is split into three parts, the first and third part of the first parent plus the second part of the second parent become the genetic heritage of the first whelp, while the remaining parts go to the second whelp;
3. *Uniform crossover*: this approach provides a higher genetic variation, since each gene of the whelp is copied – randomly – from one of the corresponding gene belonging to one of the parents. The second whelp will have the genes not chosen for creating its “brother” chromosome;
4. *Arithmetic crossover*: the offspring chromosomes are the results of some arithmetic operations on the parents’ genes (e.g. an AND operation).

For our aim is to generate the broadest diversity among monsters, we have opted for the *uniform crossover* approach. Actually, the first two techniques (*single* and *two point(s) crossover*) provide a limited variation in the genetic heritage of the offspring, while the *arithmetic crossover* is not suitable for the structure we have used to represent chromosomes (see §4).

### 3.2 Mutation

Genetic *mutation* is useful for inserting into the offspring’s chromosome some characteristics not inheritable from parents, since not present in their genetic heritage. Similarly to what happens in nature, mutations can introduce a new characteristic or modify/destroy an existing one.

In our work we have consider only the possibility to create/destroy characteristics, since modifying an existing one (e.g. the beak of a bird that increases its length from generation to generation, according to Darwin’s theory), besides requiring more complex data structures to be

managed, would not have made much sense in a typical MMOs. Moreover, representing such a mutation would create more than one headache to someone in charge of developing graphics 3D models and animations for the monsters.

## 4. Selecting and describing monsters

To provide a significant population of monsters, we have tried to describe them accordingly to the characteristic and skill structures used in the most popular MMOs and MORPGs (such as World of Warcraft). Since these games can be set in very different periods (ranging from the most remote past, to the far future), also the types of mobs present can vary widely, and may require a different representations of their genes. This implied to make some choices, such as selecting an historical setting and sticking to it.

Since the vast majority of successful video games are based on a *fantasy* setting, we have opted for it. This, inevitably, led to lose some generality in the monsters representation, but on the other side offered the advantage to guarantee coherence and meaningfulness. Moreover, a generative algorithm based on fantasy setting, probably is more likely to be inserted into a video game. Finally yet importantly, such an exploited setting offers a greater variety of ready-to-use monsters.

Figure 4 - Fantasy mobs: an Ent and a Beholder

An accurate description of mobs (e.g. numerical values for their skills) is generally difficult – or quite impossible – to extrapolate from commercial MMOs. Luckily, these games are generally more or less sophisticated derivations of paper-and-pen Role Playing Games (RPGs), such as the renowned Dungeon and Dragons (D&D) (Bartle, 2003). This offered us the opportunity to exploit the huge corpus of information about physical aspect, characteristics and skills present in the manuals of tabletop RPGs games. In particular, the description of the monsters population we have adopted is based on the mobs described in the Dungeons and Dragons (D&D) manuals: (Dungeons and Dragons, 2000, 2003). We have analyzed more than 150 fantasy monsters (see Fig. 4 for an example), and we have created a “candidate” list of monsters that could have been represented and used as input for a GAs. We have not included in the list both immortal (e.g. angels, quasi-divine creatures, etc.) and undead (e.g. zombies, vampires, ghosts, etc.) monsters: the first ones could have caused overpopulation, while the second ones usually do not reproduce (at least in a “natural” way).

Characteristic	Type	Range
Sex	physical	2
Head number	physical	0-7
Arms number	physical	0-8
Legs number	physical	0-8
Eyes number	physical	0-8
Skin colour	physical	0-8
Eyes colour	physical	8

Table 1 - Genes of the main mob's characteristics

Each monster is described by a chromosome, which maps its characteristics and skills. Characteristics can be: *physical* (e.g., number of legs, eyes colour, etc.), *natural abilities* (e.g., breathing water, ability to swim, etc.), and *magical abilities* (e.g., immunity to fire, ability to cast spells, etc.), as detailed in Tab.1. The maximum number of variations for each characteristic has been fixed to 8 (i.e., a monster cannot have 9 or 10 arms), thus constraining the possible mutations, in order to guarantee the algorithm performances.

Monsters' characteristics can be clustered into three main groups, each of which has a different relevance or goal in the reproduction process:

- characteristics that must be different in candidate parents (e.g., *sex*);
- characteristics that must be present in order to create a living monster (e.g., *type of breathing*, *number of legs* and *heads*, etc.);
- optional characteristics, useful to better define the monster (e.g., *resistance to spells*, *lycanthropy*, etc.).

The whole complex of these characteristics can be described using 37 genes, which are the basic building blocks of each monster chromosome. The dimension of each gene depends on how many *disjunctive* variations it can express. When the gene represent a non-disjunctive characteristic (e.g. the mobs breaths both air and water, like in the case of the mermaid), it has been duplicated: this solution allows the offspring to inherit none, one or both the characteristics.

Moreover, 16 more characteristics (*generation*, *current generation*, *challenge rating*, *life*, *strength*, *dexterity*, *constitution*, *intelligence*, *wisdom*, *charisma*, *armour class*, *speed*, *attack*, *reflexes*, *temper*, *will*) are necessary. Each of them is described by a number, since they may assume values too big for being easily managed by binary code: for example, the “*generation*” characteristic (which represent the maximum number of generations to which the monster is allowed to survive – i.e. it is a proxy for its lifespan) may ideally vary between 1 and infinite. As a consequence, any monster used in the GOLEM project is represented by a chromosome composed by 53 genes (37 basic plus 16 special). To notice that not all the characteristics used to describe monsters in D&D have been mapped into the chromosome, since several among them are not relevant for a MMO and/or cannot be properly managed through reproduction (e.g. *horse-riding* ability).

## 5. Creating and balancing a monsters population

Usually, GAs are used to solve optimization problems. In our work, instead, we have investigated to which extent GAs can be fruitfully exploited to generate a variety of new and unpredictable monsters for MMOs, in order to increase fun for players. To obtain this effect, our algorithm, that we have called GOLEM (Generator Of Life Embedded into MMOs), selects a male and a female candidate parent, mixes up (using *uniform crossover*) their genes, produces some mutations and creates two whelps, each of which possesses a subset of the parents' genome, plus a possible mutation. At this point, the algorithm ends, without applying any optimality criterion.

To implement GOLEM, besides creating a proper structure for representing the chromosome, we had to deal with some other design problems. Namely:

- choosing the number of whelps produced by each couple in each generation;
- defining some parameters to verify whether freshly created species are suitable for survival;
- balancing the population numerosity.

### 5.1 How many whelps?

Choosing how many whelps each couple of parents should generate in each generation has been a crucial point in the design of GOLEM. We ended up in deciding to generate *two* puppies. Actually, producing only one whelp implied a certain probability that several characteristics would have disappeared (since casually never transmitted to the offspring), thus de facto partially nullifying the effect we wanted to obtain (maximizing *variety*). On the other side, one single puppy would have meant a linear increase in the population numerosity and a better scalability of the software application. At the opposite end, a large number of puppies guarantees that practically every possible characteristic is preserved in the offspring, but also causes a steady and rapid increase in the population, which would reach its upper limit in a bunch of generations. As a result, we would end up with a group of individuals close relatives and presenting quite similar characteristics. For example: a starting population of 30 mobs, producing 8 whelps for couple in two interactions per generation, with an upper bound of 78 individuals for the population, would saturate in 3 generation. As a consequence, only 12 individuals have had the possibility to interact (around the 40% of the starting population).

### 5.2 Are new species suitable for survival?

Crossover and mutation could produce a mob with characteristics that could diverge significantly from those of its parents. Since the mob should be inserted in a game world, it is necessary to verify its “credibility”. In particular, we want to be sure that the newly created specie is able to survive in its *habitat*. Think, for example, to the offspring of a mermaid and a human: it could be born on the mainland, but be suitable only for marine life. In the GOLEM project we have considered four possible habitats: *forests*, *mountains*, *lava flooded areas* and *water*. Whelp’s characteristics that must be checked against its habitat to verify its survival probabilities are: *breathing* (e.g. a mob breathing water will not survive in a forest) and *movement type* (e.g. a mob only able to swim, will not survive on a mountain). To notice that several monsters could have more than one respiratory system (e.g. mermaids), thus they suffer some *malus* when outside their primary habitat, but they do not die. Moreover, some other characteristics may provide a *bonus/malus* to the whelp according to the surrounding environment: fins, gills, scales (both fish and dragon-like), feathers and fur.

### 5.3 How many individuals in the population?

Although some whelp will die due to unsuitability to the environment, it is necessary to keep a control on the population numerosity, in order to avoid overpopulation. This implies defining an upper bound to the number of individuals

alive, and some criteria to “kill” several mobs when their number reaches a certain threshold. For this reason, we have introduced both death *by old age* and *by chance*.

**5.3.1 Death by old age.** In this case, for each generation and mobs, GOLEM verifies whether the mob has reached the end of its lifespan (in terms of number of generations to which it can survive). In particular, each monster has a *longevity* that can assume one value among *short*, *medium* and *long*, to simulate the different lifespans of different monsters.

**5.3.2 Death by chance.** In a game world, a mob can die also because it has been killed by a player (and generally this is one of the main goal of players!) or, in few cases and under special game design conditions, due to illness. To avoid under populating the world, GOLEM applies casual death only when the population numerosity reaches the 70% of its maximum. This threshold has been defined by trials. To decide whether a mob should die by chance, we have grouped monsters into four categories, according to their “*challenge rating*” (a numerical value representing a proxy of the monster hardness and stamina, usually adopted in large number of RPGs): stronger mobs get killed with a lower probability. Once the challenge rating level has been (randomly) chosen, an individual in that category is randomly extracted to die.

## 6. The GOLEM algorithm

The GOLEM algorithm takes as input a starting population (whose numerosity grows constantly, generation after generation), and executes four main functions: *selection*, *crossover*, *mutation* and *evaluation*, after which a new generation is added to the population. All the functions have been implemented using C++, since it is one among the most diffused languages in the video game industry.

### 6.1 Selection

This function main goal is to select couples of candidate parents. Its first action is verifying whether some mobs should die by old age or by accident. That is to say, firstly GOLEM compares each mob lifespan against the current generation number, and then verifies if the population numerosity has reached the 70% of its maximum value. If yes, death by chance occurs as described in §5.3.2. Once this verification is concluded, the function selects candidate parents: if the “challenge rating” of the two mobs in a couple is too different, they do not mate. This check simulates the fact that, in a fantasy world, powerful mobs (e.g. a dragon) generally are uninterested in mating with weaker creatures (e.g. a kobold). The challenge ratings of our mobs have been grouped in four main classes: *low*, *medium*, *high*, *invincible*.

### 6.2 Crossover

The function takes as input the chromosomes of the parents selected by the Selection function and operates a *uniform crossover* (§3.1) on them. The chromosomes of the two resulting whelps are randomly filled with their parents’ genes.

### 6.3 Mutation

Once we have the offspring chromosomes, we apply *mutation* in order to increase variety and avoid the possibility of obtaining a population too uniform. GOLEM mutation changes randomly the value of *one* (and only one) randomly chosen characteristic; the mutation happens in the 90% of the cases, in order to add variation in the population. The possibility to generate randomly exactly the starting value for a characteristic is not excluded; hence, obviously, the probability to have an actual mutation increases with the length of the string representing the specific characteristic. Lethal or impairing mutations have not been introduced, since it would not have made any sense in a population of mobs for a video game.

### 6.4 Evaluation

It is now necessary to evaluate whether whelps can survive the habitat were they are born, as described in §5.2. If yes, the function checks if some *bonus/malus* applies: e.g., a water-born mob devoid of fins and scales can survive in the sea, but is weakened; as a consequence its skills (which are represented by numerical values – see §4) will suffer a 20% *malus*. The evaluation is applied to every whelp created in the current generation.

### 6.5 Ending condition

Generally GAs end when a certain condition – which determines the “optimum solution” – is met. The GOLEM algorithm is not intended for optimization, nor it has to evaluate the quality of the offspring (our goal is to maximize diversity), hence its ending condition is met when it reaches a predefined number of generations.

### 6.6 GOLEM fine tuning

In the definition of GOLEM we had to face several criticalities. In particular, we had to fine-tune by hand the value of several parameters in order to obtain useful results (in terms of mobs generated) and good performances. As a matter of fact, the outcomes generated by the algorithm are affected by:

- the number of characteristics represented by the chromosome;
- the probability to have a mutation;
- the probability to have death by chance;
- the probabilities, for a low/medium/high/invincible *challenge rating* mob, to be chosen for death by chance (respectively 0.8, 0.6, 0.3 and 0.1);
- the maximum numerosity of the population;
- the number of generation to produce;
- the number of whelps for each mating.

## 7. GOLEM primary results

As an example of what can be obtained from GOLEM, let's see what happens when crossing two very different monsters: a griffin and a goblin (see Fig.5). By recombining and mutating their chromosomes, we obtain two whelps, whose

genome differs from those of their parents respectively 18.8% and 28.3% (see Tab.2 – not binary values in greyed cells).

Figure 5 - A griffin and a Goblin

To estimate the level of diversity among generations, the variation should not be calculated taking as reference the starting couple, since offspring genes, after a certain amount of generations, could – by chance – configure (partially or completely) exactly as those of the ancestors. Consequently, these variations would not be included into the total amount of variations. Hence, the degree of diversity provided by the algorithm should be evaluated taking into consideration the differences between each couple of two subsequent generations. If we adopt this approach, we can notice that, with a starting population composed by 2 individuals, after 10 generations, the average genetic difference among two subsequent generations is of 7.1 genes (that is to say the 13%), while after 20 generations this value increases till the 7.15 (13.4%). This value then decreases in the following generations till it becomes constant, due to an increasing similarity in the genetic heritage (see Fig. 6; note that, since the comparison is made on only 1 puppy, the figure shows only half the generations on x axis). After 100 generations, the difference between parent and son is only of 1.9 genes (3.5%).

If the starting population increases to 18 different individuals, the algorithm performs better. As Fig.7 shows, the difference among contiguous generations is of 7.4 genes (13.9%) on average, and, even after 100 generations, the genetic mixing is still substantial.

After a dozen of tests, we have established – by trials and errors – that GOLEM performances are at their best in the following situation:

- population starting numerosity: 18;
- maximum population: 200 individuals;
- number of generation: 100;
- number of whelps per generation: 4 or 8;

in this case, the final numerosity of the population is 170, with a good diversity among mobs.

In the case a larger number of monsters is required, a quite good performance is provided by this configuration:

- population starting numerosity: 18;
- maximum population: 400 individuals;
- number of generation: 150;
- number of whelps per generation: 4 or 8;

in this latter case, the final numerosity of the population is 330, with a quite good diversity among mobs: approximately 30 individuals have a very similar genome (that is to say the difference is no more than 2 genes), thus only the 10% of the population is represented by very similar – or even identical – monsters. A further increase in the population numerosity causes the appearance of too many very similar chromosomes.

Characteristic	Goblin	Griffin	Whelp 1	Whelp 2

Resistance to spells	0	0	0	0
Resistance to dispel	0	0	0	0
Damages reduction	0	0	0	0
Poisonous	0	0	0	0

Table 2 - Genes of a Goblin, a Griffin and of their offspring

Nonetheless, it is important to underline that a similar chromosome – or even identical – not necessary implies that the mobs are “the same”. For example, a population whose maximum is fixed to 250 individuals produces 218 whelps in 100 generation (4 or 8 puppies for each generation): among them only the 20% have similar chromosomes. In fact, genes describing physical traits can be described in the same way monsters that have very different skills; e.g. both a panther and a mouse have four legs, fur, a tail, and breathes air, but their strength and hazard is deeply different.

Figure 6 – Genetic difference (starting population: 2)

Figure 7 - Genetic difference (starting population: 18)

## 8. Conclusions and future development

In this work, we have tackled the issue of increasing diversity and unpredictability of mobs by developing an ad-hoc GA, we have called GOLEM – Generator Of Life Embedded into MMOs. In particular, we have provided a detailed general-purpose description of fantasy creatures, based on genes and chromosome, developed functions aimed at generating new species by uniform crossover and mutation on the genome of monsters parents, implementing an overall logical architecture that partially mirrors a biological ecosystem. Only several specific aspects of an actual ecosystem have been modelled: those relevant for mimicking a meaningful virtual environment for a video game. We have then tested and fine-tuned the algorithm in order to obtain outcomes – in terms of monsters population – useful for a MMOs.

The GOLEM project provides only the GA algorithm and the database of the monsters characteristics used to create the chromosomes. To be embedded into an actual MMOs – or,

more in general, in a video game –, it could, and should, be expanded in many directions. In particular, we have envisaged several possible future developments for the GOLEM algorithm:

- adding *dominant* and *recessive* genes: this development needs a careful design and a fine tuning, since it may imply a decrease in the number of characteristics actually expressed (*phenotype*) by the genetic heritage (*genotype*);
- introducing more significant mutations, which, e.g., may increasingly modify in time a specific characteristic;
- adding interdependence among specific genes: e.g. a mobs able to breath water will also have gills;
- refining the death by old age/by chance function, to better simulate monster aging (e.g. older monsters will not reproduce and will have more chances to succumb by illness).

Moreover, several refinements and simulations will also be developed to test GOLEM performances under the following conditions:

- the algorithm is embedded into a client-server architecture, designed to support a MMO, hence real-time interactions;
- the game environment is populated by players, which interact with the mobs (and kill them);
- the number of players varies (hence the population of the monsters should adapt).

Last, but not least, some corollary – but nonetheless of fundamental relevance for using GOLEM in a video game – imply such complex issues to generate several autonomous research areas:

- creating tools able to provide automatically – and in quasi real-time – graphic 3D representations and animations of GOLEM-generated monsters;
- adapting GOLEM as a basis for generating game maps directly related to the monsters characteristics;
- measuring the impact of monsters diversity generated by GOLEM on players' overall satisfaction with the game.

# Evolving Behaviour-Dependent Strategies in Agent Negotiations

Darius P. Falahat, Enrico H. Gerding and Markus Brede

Electronics and Computer Science,  
University of Southampton, SO17 1BJ  
dpf1g11@ecs.soton.ac.uk

## Abstract

We use genetic algorithms to evolve trading strategies for iterative bilateral negotiations between buyers and sellers. In contrast to previous work we evolve purely reactive strategies that base decisions on memories of behaviour in previous negotiation rounds. We find that simulations lead to three main types of behaviour: (i) cooperative outcomes in which bargaining leads to an agreement and equal sharing of profits, (ii) uncooperative outcomes in which negotiations are not successful and (iii) outcomes in which one party profits at the expense of the other. The frequencies of each type of behaviour vary when the probability for negotiations to terminate is changed, confirming our hypothesis that cooperation should decrease as this break-off probability increases. Comparisons of the results to tit-for-tat (TFT) strategies and previous research on the iterated prisoner's dilemma (IPD) are used to understand simulation results, and we observe the emergence of TFT behaviour during periods of agent cooperation.

## Introduction

Trading over the internet and other communication networks continues to grow ever more prevalent in both high-income economies and emerging markets. Research in e-commerce is relevant to high frequency trading, supply chain management and many areas that involve some sort of online transaction. Automated negotiation is central to many of these systems. The application of game theory to automated negotiation is well-established (Binmore & Vulkan, 1999) with practical uses in e-commerce realised early on (Oliver, 1996). The core mechanics of this type of negotiation are retained in a widely used, simple bilateral negotiation model with alternating-offers (Rubenstein, 1994). We use this framework in conjunction with evolutionary computation to make a fresh contribution in a field neglected by the literature in recent years: behaviour-dependent negotiation.

Previous work (Gerding et al., 2004) has focused on using GAs to investigate the emergence of time-dependent negotiation strategies. In the framework of Matos et al. (1998) and Faratin et al. (1997), an agent's strategy can be determined by closeness to a negotiation deadline (time-dependence), the scarcity of a diminishing re-

source (resource-dependence) and the actions of an agent's opponent (behaviour-dependence). However, regarding behaviour-dependence the authors only consider variations of TFT. The intention of this paper is to address this gap in the literature and develop behaviour-dependent negotiation. Building on previous work in the context of the IPD (Lindgren, 1992) we aim to test for the emergence of cooperative behaviour within a framework of reactive strategies.

## Related Research

Automated negotiation has been shown to be vital to e-trading (Sierra et al., 1997) and the use of GAs to identify the most successful negotiation strategies has long been widespread (Matos et al., 1998). GAs use the powerful processes observed in biological evolution: selection of the best-performing (fittest) individuals to replace a population, combined with a small probability of these new individuals undergoing mutations in order to generate diversity and explore the strategy space. GAs have been popular in many fields because they make no assumptions about agent rationality, or the fitness landscape in general. The propagation of agent strategies into new generations is purely based on their fitness.

The complexity and capability of these agent-based models has progressed over time such that, in addition to bargaining over the price of goods (single-issue negotiation), agents can argue over additional properties such as deadlines, cope with multi-issue negotiation (Gerding et al., 2000) and incomplete information (Fatima et al., 2004). This model attempts to take a simple approach that only involves bargaining over a price for the goods; fitness is simply defined in terms of agent utility.

In the context of iterated social dilemma games like the IPD, the situation we consider has been studied extensively by the artificial life community. The prisoner's dilemma is a classic one-shot game, where cooperation rewards higher utility but the rational choice is to defect. In the IPD agents play each other repeatedly, which introduces the potential for more complex behaviour, such as punishment for defection in previous games. Theoretically for a finite number of

games, backwards induction implies that the rational choice is to defect each time, although this reasoning does not hold if the number of negotiation rounds played is uncertain and not a priori known to agents. When strategies were tested against each other in an IPD tournament (Axelrod, 1980), the most effective and robust strategy was for an agent to cooperate on the first move and then retaliate with the opponent's previous action. This strategy, TFT, was successful because it rewarded cooperation and punished defection. It should be noted that with the IPD there is a payoff at the end of every negotiation round, whereas in the bargaining model we consider there is only a chance of a payoff at the end of a full negotiation between two agents. Hence results from the IPD can not be translated directly to the simulation results we present in this paper.

### Contributions

We have seen that most related research on bilateral negotiation has focused on time-dependent strategies. Our main contribution is to remedy the lack of behaviour-dependent research: the actions of the agents in this model depend entirely on their own past behaviour, and their opponent's past behaviour. The approach we take is similar to Lindgren (1992), where the author models a single population of agents playing the IPD against each other. Lindgren allows the mutations to make the agent strategies more complex, and finds that selection favours cooperative strategies. This exploration of the strategy space via mutations allowed the author to observe extinctions, periods of stasis and other phenomena. Our research also uses a one-population model, but the agents interact via the bilateral negotiation method instead of the IPD. We define cooperation as the sharing of profits equally, meaning exactly equal utility for both agents. Furthermore mutations are only used to randomly select among existing strategies, not to change the size of agent chromosomes. This means the strategy space remains unchanged throughout a simulation, unlike in Lindgren (1992) where the author allows the strategy space to increase.

Despite using a simple negotiation framework, the model produces agent strategies that can be compared to well-known results from the literature (see Results section). The extensibility of the model means the existing framework can be easily built up to further complement the automated negotiation literature from a behaviour-dependent perspective.

### Overview

The following section will describe the model in detail, first tackling the negotiation framework and then explaining how the GA works. The section after that reports the results, stating the experimental setup and the parameters used in the simulations. We then present and discuss the observed types of agent behaviour, including analysis of a frequency distribution showing how the different classes of evolved behaviour change over time. The final section summarises the

paper including the results, and we suggest several avenues for future research.

## Model Description

The model can be understood best by treating it as two distinct components: a negotiation framework and a GA. This section will describe how these components work in detail (see Figure 1 for an overview). The negotiation framework has the bilateral alternating-offers protocol at its core, but the discussion will also include a description of agent strategies and their time-independent nature. The GA is essentially a search algorithm that is applied to the framework; it finds the best performing agents and ensures there is a high probability of them being passed onto the next generation.

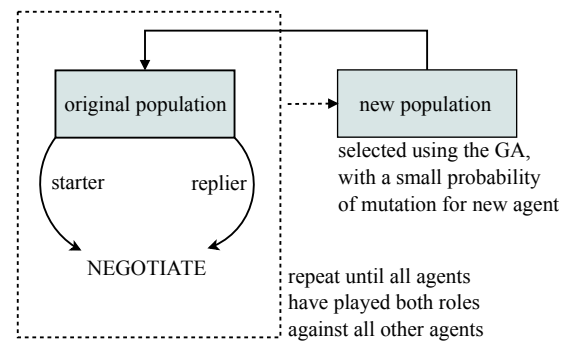

Figure 1: An overview of the interaction between the negotiation framework and GA. One full circuit of the diagram comprises a single *generation*, i.e. the complete interaction and replacement of an agent population.

### Negotiation Framework

The bilateral negotiation protocol involves two agents bargaining over goods. The mechanics of how they make offers, counter-offers and contemplate agreement varies considerably over the field of research. In this paper we use a specific protocol with a small strategy space, which keeps analysis relatively simple.

Negotiation between two agents means a Buyer agent and a Seller agent proposing offers and counter-offers to each other, in an attempt to agree on a price for the item. The Buyer initiates proceedings and the Seller replies with a counter-offer. During a negotiation, the Buyer will always begin by offering 0 for the item, while the Seller will make an initial offer of 10. An agent's reserve price is defined as his opponent's initial offer, so the price of the goods stays between the range  $[0, 10]$  even though there are no explicit constraints on its value. To simplify matters, the agreed price is converted to utility in the following way. If the Buyer accepts the Seller's offer,

$$U^b = O_{s \rightarrow b}^t \quad (1)$$

$$U^s = 10 - O_{s \rightarrow b}^t \quad (2)$$

where  $U$  is an agent's utility, and  $O_{s \rightarrow b}^t$  is an offer from the Seller ( $s$ ) to the Buyer ( $b$ ), at negotiation round  $t$ . Hence utility for both agent types follows the same convention. An inability to come to an agreement results in both agents being punished with zero utility.

There are only two actions, concede and non-concede, available to agents in this model because only two are necessary for bilateral negotiation. Including further actions would be interesting but an area for future work; a spartan philosophy was used for the base model in an attempt to reduce unnecessary complexity. The actions are the same for Buyers and Sellers, but the concede action has different outcomes depending on the agent.

For the Buyer the concede ( $C$ ) and non-concede ( $N$ ) actions are as follows,

$$C : O_{b \rightarrow s}^{t+1} = O_{b \rightarrow s}^t + 1, \quad N : O_{b \rightarrow s}^{t+1} = O_{b \rightarrow s}^t \quad (3)$$

While for the Seller,

$$C : O_{s \rightarrow b}^{t+1} = O_{s \rightarrow b}^t - 1, \quad N : O_{s \rightarrow b}^{t+1} = O_{s \rightarrow b}^t \quad (4)$$

This incremental approach to modifying offers is used instead of other approaches, such as making a complete offer every time, because it restricts the strategy space and limits the complexity of the model.

The alternating-offers protocol is sequential in nature, which means the Buyer will make an offer, followed by a counter-offer from the Seller. The Seller compares the utility it could get by accepting his opponents offer, to his own counter-offer. If the Buyer's offer is more favourable, the Seller will accept. Otherwise, the Seller will decline and the process will continue. The negotiation method  $M$  is described in more detail in Eq. (5) from the perspective of a Buyer  $b$  who has received an offer  $O_{s \rightarrow b}^t$  from a Seller  $s$  at round  $t$ ,

$$M^b(O_{s \rightarrow b}^t) = \begin{cases} Quit & \text{if } t > t_{max} \\ Accept & \text{if } U^b(O_{s \rightarrow b}^t) \geq U^b(O_{b \rightarrow s}^{t+1}) \\ O_{s \rightarrow b}^{t+1} & \text{otherwise} \end{cases} \quad (5)$$

where  $t_{max}$  is the deadline. The notation used to describe the bilateral negotiation protocol is borrowed from (Fatima & Wooldridge, 2002). To lessen the impact of a hard deadline on the negotiation mechanics, the model uses the equivalent method of a break-off probability. This means there is a very small chance of the negotiation ending in each round.

Another motivation for using break-off probabilities is that this removes defection via backward induction (see Related Research) as a rational choice, because agents do not know how long a negotiation will last in advance. Using a break-off probability  $p$ , we have the expected utility,

$$\langle U \rangle = U \left[ 1 - (1 - p)^T \right] \quad (6)$$

where  $T$  is the number of negotiation rounds until agreement. The break-off probability  $p$  can be varied: this is likely to have an effect on cooperation if cooperative strategies evolve. Raising the break-off probability limits the time left to negotiate, which would mean fewer strategies can lead to equal sharing, lowering chances for cooperation to develop. We would therefore expect to see less cooperation at higher break-off probabilities, and an increased likelihood of negotiations that end with no agreement at all.

The novel extension of this model involves each agent having a memory consisting of its own and its opponent's previous offers. These memories are central to the strategies that define agent behaviour. An agent's strategy is a mapping of every possible memory to the actions concede ( $C$ ), or non-concede ( $N$ ). These actions correspond to those defined in (3) and (4). Every agent's strategy holds the information shown in Table 1 below.

		Initial		Main			
Buyer	Memory	$S$		$C, C$	$C, N$	$N, C$	$N, N$
	Action	$C$ or $N$					
Seller	Memory	$C$	$N$	$C, C$	$C, N$	$N, C$	$N, N$
	Action	$C$ or $N$					

Table 1: A representation of how agents' strategies are encoded. The order of memories is important:  $C, N$  means an agent conceded and his opponent did not.  $N, C$  means the opposite.

It should be noted that every agent carries a Buyer and Seller genome, as in Table 1. These genomes are separate: the Buyer genome is used when the agent plays as a Buyer, and similarly for the Seller genome. In a single generation, every agent will play once in both roles. An agent's utility is calculated as the average of the utility from its roles as a Buyer and Seller.

In the first round of a negotiation, the Buyer has no real memories to base an action on. So the special initial  $S$  memory is used by the Buyer, only for the first round. In the second round, the Seller does not have a full memory, only a memory of its opponent's move. This means the Seller needs its own initial special case, which depends on what the Buyer did. After the two initial offers, an agent's decision depends on any combination of its own last move, and its opponent's.

Throughout this paper we assume that agents have a one-step memory. This means agents only remember the pre-

vious round. A strategy with two-step memories would be much longer: the first two possible memories in the main body would be  $(CC, CC)$ ,  $(CC, CN)$ , and so on.

### Genetic Algorithm

Selection of the fittest agents (those with the highest utility) is achieved using fitness proportionate selection, also called roulette wheel selection in the literature. Unlike some other types of GA, there is still a small probability of choosing less fit agents. This is important because a strategy that is weak against particular strategies may be strong against others, making it slightly more realistic than completely discarding unfit strategies as with truncation selection. See the algorithm below for pseudocode showing where the GA fits in relation to the negotiation framework and the rest of the model.

---

**Algorithm 1** A simplified representation of the one-population model and GA.  $n_{max}$  is the agent population and  $x_{max}$  is the number of generations for which the simulation continues. Offers, counter-offers and utility calculations are made in the NEGOTIATE subroutine. All agents play each other in both Buyer and Seller roles, but are not allowed to play against themselves.

---

```

Require:  $n_{max}, x_{max}$ 
while  $n < n_{max}$  do
   $agents \leftarrow \text{INITIALISEAGENTS}()$ 
  while  $x < x_{max}$  do
    if  $\text{AGENTSPLAYED}() = \text{False}$  then
       $buyer, seller \leftarrow \text{PICKAGENTS}(agents)$ 
       $\text{NEGOTIATE}(buyer, seller)$ 
       $\text{RESETMEMORIES}(buyer, seller)$ 
    end if
     $\text{GETUTILITY}(agents)$ 
     $agents \leftarrow \text{SELECTION}(agents)$ 
  end while
end while

```

---

Agents also have a small chance of undergoing single-gene mutation during the selection process, and are given a smaller probability of being completely replaced by a new random agent, to properly explore the strategy space without having to run extremely long simulations. Gene mutations are simply the possibility of an action in an agent's strategy to switch randomly. For example, a Buyer's initial move could change from  $N$  to  $C$ . If the Seller's two initial moves (see Table 1) are identical, the change will make no difference to the negotiation. On the other hand if they are different, it could change the effective behaviour completely. Since mutations can affect genes that are not used during negotiations, it is possible that mutants could invade populations via neutral drift. This is a possibility because certain types of behaviour use very few genes of an agent's genome (e.g. Table 2 in the Results section), making them

potentially vulnerable to drift.

## Results

In this section, the different types of agent behaviour are categorised and the change in strategies, and agent utilities, over a simulation are plotted. The stability of the distinct negotiation scenarios are analysed, and some specific strategies are discussed in depth. Finally, the relationship between cooperative behaviour and the break-off probability is plotted and explained.

### Experimental Setup

The key parameters for the following simulation results (unless specified otherwise) are given below :

- Population size 100.
- Simulation length of 2000 generations.
- Mutation rate of  $10^{-5}$  for every gene per generation, and  $10^{-4}$  for the mutation of an entire agent. These values were arrived at by slowly decreasing from a large mutation rate, to reach a point where noise from mutations did not dominate the system. For example, there is approximately one gene switch per population every 10 generations, and the introduction of a new randomised agent happens roughly a few times over 100 generations.
- Single time-step memories, i.e. agents only remember the previous negotiation round.
- A break-off probability of  $p = 0.005$  (see Eq. (6)) is used for the simulations shown in Figures 2, 3 and 4. This probability gives agents 200 negotiation rounds on average to come to an agreement. Figure 6 uses a larger break-off probability of  $p = 0.05$  and the parameter is varied in Figure 5.

### Strategy Analysis

Three main negotiation outcomes have been observed in the model. We define these as follows:

- **Domination** is the category of outcome where one agent type has finished a negotiation with a higher utility than the other.
- **Cooperation** is the label for negotiations that finish with both agents walking away with equal utility, if agent utilities are above zero.
- **Zero Utility** outcomes are when both agents finish the negotiation with no utility. This outcome represents a failure to negotiate successfully, so it is treated as distinct to co-operation.

Figure 2: A long simulation run showing the change in agent utilities over time, and the volatility caused by the persistent instability of strategies.

A long simulation using the parameters set out above is shown in Figures 2 and 3. In our analysis of the negotiation outcomes we use two types of plot to clarify the agent dynamics. Figure 2 is a plot showing the average expected utility against the number of generations. The utilities presented in the plot were calculated using Eq. (6) for each agent, with a different utility value for the Buyer and Seller agent types. The expected utilities are then averaged over the population every generation to produce the following plots. Since utilities can range from 0 to 10, the expected utilities will always be less than 10, and often considerably less.

Figure 3 shows the fraction of negotiation outcomes at every generation. Every negotiation is classified as one of the three categories mentioned previously. This type of plot is more sensitive to the strategy dynamics, while the utility plots give a clearer idea of how agents are being selected over the generations.

The most obvious property of Figure 3 is that the simulation never reaches a stationary point, i.e. the strategy fractions never stabilise. In situations where the zero utility (total defection) strategy is in the majority, this lack of stability could be because these agents are scoring no utility, so the population can be invaded by mutants that use any other strategy because no strategy can perform worse. This behaviour highlights a difference to the IPD where defection clearly matters, because agents have the opportunity to punish their opponent straight away.

Invasions of these strategies consist of a build-up of mutants, followed by a swift replacement of the population as soon as utility-scoring mutants start to be selected. Although

	Action	<i>N</i>	<i>N</i>	<i>C</i>	<i>N</i>	<i>C</i>	<i>N</i>

Table 2: A strategy table corresponding to the most stable kind of zero utility strategy. Due to becoming locked in a cycle, only the actions in bold are taken by the agents.

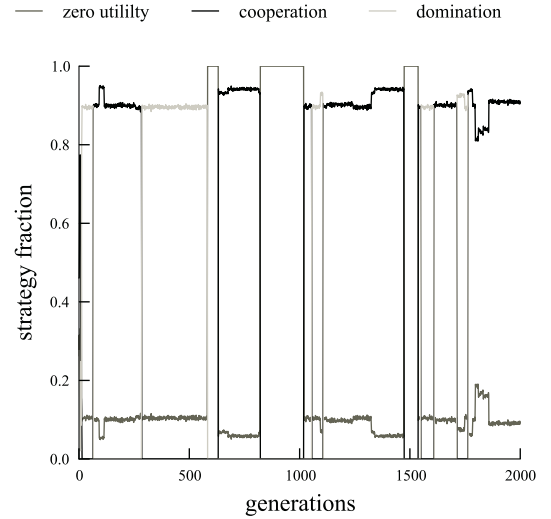

Figure 3: A plot showing the strategies corresponding to the simulation in Figure 2, displaying the changes in agent behaviour.

zero utility strategies are all inherently unstable, some are more resistant to invasion than others: an interesting case is that of a population using the genomes in Table 2.

The most common type of behaviour after the initial stage of the simulation is cooperation. There are many types of strategy that can lead to cooperative behaviour, including all-concede strategies and TFT-like behaviour. Table 3 is an example of the emergent TFT strategies we observed during periods of cooperation.

		Initial		Main			
Buyer	Memory	<i>S</i>		<i>C, C</i>	<i>C, N</i>	<i>N, C</i>	<i>N, N</i>
	Action	<i>C</i>		<i>C</i>	<i>N</i>	<i>C</i>	<i>N</i>
Seller	Memory	<i>C</i>	<i>N</i>	<i>C, C</i>	<i>C, N</i>	<i>N, C</i>	<i>N, N</i>
	Action	<i>C</i>	<i>C</i>	<i>C</i>	<i>N</i>	<i>C</i>	<i>N</i>

Table 3: A strategy table corresponding to cooperative behaviour. Both agents employ TFT-like strategies to arrive at a cooperative outcome.

The Buyer uses a pure TFT strategy, as it initially cooperates and thereafter responds with its opponent's previ-

ous move (Axelrod, 1980). The Seller effectively follows the same strategy, resulting in mutual conceding until an equal agreement is reached. For the Seller's strategy to be pure TFT, its initial actions would need to be  $C \rightarrow C$  and  $N \rightarrow N$ . The TFT strategies are not stable, possibly because groups of TFT agents are vulnerable to conceders creeping into the population via neutral drift. The concept is similar to the findings described in Nowak & Sigmund (2005): once non-discriminating conceders invade a population, they are in turn vulnerable to non-conceders (defectors). This has the effect of temporarily replacing a cooperating population with a dominating Buyer or Seller population. A sharp transition of cooperation to domination (and the reverse) can be seen at certain points in Figure 3; the abrupt nature of these transitions may be due to the relatively small size of the agent population.

We have seen from the strategy tables that, during a negotiation, an agent's actions are only determined by a fraction of its entire strategy. By tracking all possible actions available to agents and comparing this to what agents are doing, we can investigate the vulnerability of a majority-conceder population and check for neutral drift. The top plot of Figure 4 shows the fraction of all possible actions in every agent's strategy. The bottom plot shows actual agent behaviour. For the first 300 generations, as cooperative behaviour increases the fraction of concede actions also increases. Shortly after 300 generations have passed, these majority conceders are exploited: this can be seen in the dip of cooperative behaviour in the bottom graph and the corresponding reduction of conceders in the top plot. An indicative example of the neutral drift effect can be seen in the period between 400 and 600 generations, where non-conceding actions increase until they represent over 70% of all actions despite the prevalence of cooperative behaviour.

The analysis so far has focused on simulations that use a low break-off probability. Figure 5 tests our earlier prediction that higher break-off probabilities, corresponding to shorter negotiations, would mean cooperation has a lower chance to evolve. The figure was generated by recording the outcome of each negotiation (cooperation because an agreement was reached, or zero utility because negotiation terminated before agreement) every 100 generations. The fraction of each outcome was calculated at the end of the simulation, and this result was then averaged over 10 simulations to account for variance.

As expected, we find that the fraction of cooperative games with a *small* break-off probability is notably larger than when a larger break-off is used. Furthermore, Figure 5 shows zero utility outcomes are not typical until the break-off probability is increased: the trend for this type of behaviour is roughly inversely proportional to the fraction of cooperative outcomes.

Figure 6 illustrates this point further, showing how the zero utility outcomes take precedence when there is less time

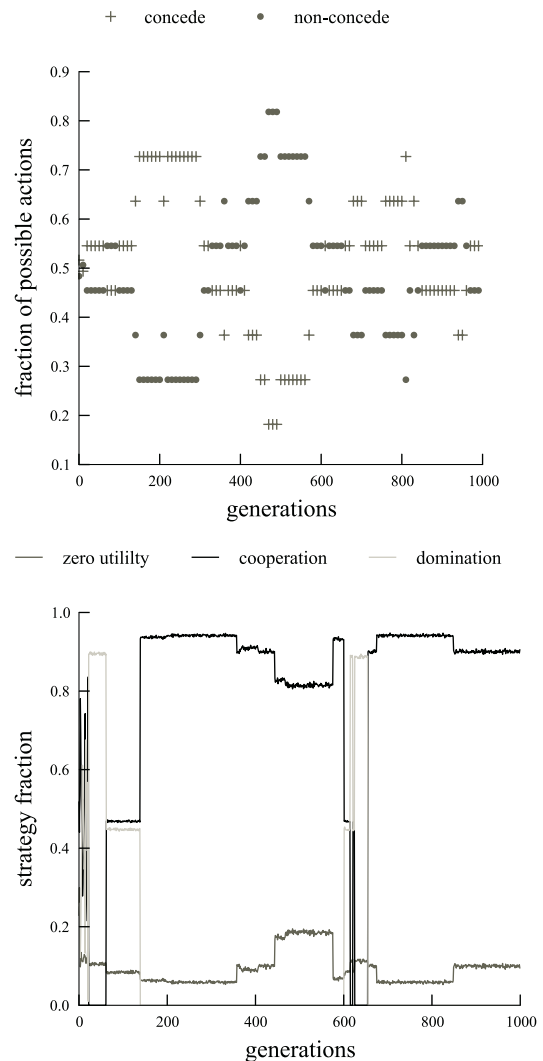

Figure 4: Top: A plot showing the fraction of possible actions for all agents over 1000 generations. Bottom: The behaviour of agents throughout this simulation.

to reach an agreement. The stark difference between Figures 3 and 6 makes sense because cooperative negotiations, which can show transient TFT-like behaviour, are often more complex (since they are discriminatory) and thus need more time to come to an agreement. Non-discriminatory strategies, such as pure defection that results in zero utility outcomes, thrive when there is less time to negotiate.

## Concluding Remarks

We built a model using evolutionary algorithms and the bilateral negotiation framework with alternating-offers protocol. Motivated by the literature discussed in the introduction and the relative lack of research on behaviour-dependent negotiation, agents were given behaviour-dependent strategies

Figure 5: A plot showing the fraction of cooperative and zero utility outcomes as a function of the break-off probability. The error bars give the standard deviation for every averaged point.

that base their actions on the behaviour of their opponents. These reactive strategies were evolved and agents selected based on their performance against all other agents in the population.

Three distinct types of negotiation outcomes were observed: cooperation, zero utility and domination outcomes, although the first two types were far more common overall. Simulations proved to be unstable even when left to run for several thousand generations; this is likely due to the neutral drift discussed earlier. Analysis of agent strategies revealed the emergence of TFT-like behaviour during periods of cooperation, although direct comparisons with TFT strategies in the IPD are not possible due to the different way pay-offs are handled. In particular, the concept of *cooperation* as discussed in this paper refers to the bilateral agreement on a price for goods; this is not entirely analogous with its meaning in the evolutionary game theory literature. Finally, the assumed relationship of cooperative behaviour with the break-off probability was verified: cooperation is observed more often when negotiations can continue for a longer period of time.

Although this paper was partly motivated by research that used game theoretic concepts like the IPD, our model is not limited to applications within evolutionary game theory. The negotiation framework can essentially be used with any search algorithm in order to select the agents that perform best, not only a GA. The results reported in this paper validate our model as an effective way to investigate the emergence of cooperation in the context of a sequential, bilateral bargaining framework.

Figure 6: The change of strategy types over time, using a high break-off probability ( $p = 0.05$ ) and otherwise identical parameters to the simulation shown in Figure 3, where the break-off probability was lower ( $p = 0.005$ ).

## Future Work

In this paper we developed a general modelling framework that allows for straightforward extensions in several directions. The first priority in future work would be to verify if it is possible to produce evolutionary stable strategies in our model. One aspect worth more detailed investigation is that of longer agent memories. So far preliminary results from doubling agent memories have mainly shown an extended initial period of noise, before the simulation continues into the familiar patterns of constant strategy invasions discussed above. However, an evolutionary stable solution should not be ruled out and there may be potential in an analytic approach due to the relatively small strategy space.

There are also many ways of increasing the strategy space, such as adding a third action. An interesting possibility is to make it a random choice between the existing two actions. This would allow us to explore if deterministic strategies are more favourable when pitted against unpredictable agents. Explicitly expanding the strategy space can be done by making time a parameter of the agent strategies, making the model both behaviour- and time-dependent. Currently a strategy is a single line of mappings; introducing time would effectively add another dimension, giving a line of possible actions for every round until the deadline.

# Behavior as broken symmetry in embodied self-organizing robots

Ralf Der and Georg Martius

Max Planck Institute for Mathematics in the Sciences, Leipzig, Germany  
 {ralfder—martius}@mis.mpg.de

## Abstract

Self-organization—ubiquitous in nature—is a major challenge for both artificial life and modern robotics offering intriguing perspectives for practical applications utilized so far only incipiently. There is some progress, though, in formulating general objective functions for driving systems into self-organization (SO). Based on general principles like information maximization, these approaches are domain invariant and free of arbitrariness. However, and this seems to be a major source of concerns, if nothing is specified from outside, will SO simply make the robot an arbitrary subject that is completely unpredictable in its behaviors and thus rather a thread than a hope. The aim of this paper is to show that this attitude is not justified. Instead, we develop an understanding of what happens if the system is self-organizing, what the role of the embodiment is and how we can find clues for predicting and shaping the behavior patterns emerging in a genuine SO scenario. The approach is based on a new unsupervised learning rule staging two antagonistic activities—driving systems towards instability while preserving the physical symmetries of the system as much as possible. This leads to spontaneous symmetry breaking, the leading phenomenon of SO known from nature that has been overlooked by the robotics community so far. It is shown by a number of examples that the unsupervised learning rule induces an amazing variety of behaviors—patterns in space and time that can be interpreted as broken symmetries.

## Introduction

Self-organization (SO) is a ubiquitous phenomenon in nature and a promising challenge to the creation of artificial autonomous systems. In particular, in embodied artificial intelligence, SO may provide an essential progress in the realization of embodied control. Viewing a robot in its environment as a complex dynamical system, SO can help to let highly coordinated and low dimensional modes emerge in the coupled system of brain, body and environment. In this way, instead of being programmed for solving a specific task, the robot may find out by itself about its bodily affordances and then, in a second step, one may focus on the exploitation of the emerging motion patterns—by guiding the SO process into the directions of potential benefits.

While there are many approaches toward structural SO, in particular self-assembly, the SO of behavior still is con-

sidered more as wishful thinking than as a true and systematic approach toward autonomy. A principled way toward the SO of behavior faces essentially two challenges. One is how to organize a robotic system in such a way that it starts to self-organize its behavior. Actually, the situation in that point is not too bad. There are several approaches based on formulating objective functions (OF) for SO. In recent years, several such OFs have been proposed, ranging from the maximization of predictive information Ay et al. (2008); Der et al. (2008); Ay et al. (2012); Martius et al. (2013) or empowerment Klyubin et al. (2005, 2007); Anthony et al. (2009); Jung et al. (2012), to the minimization of free energy Friston and Stephan (2007); Friston (2012, 2010) or the so called time-loop error in the homeokinesis approach Der (2001); Der and Liebscher (2002); Der and Martius (2012), see also Prokopenko (2008, 2009) for more details on how to organize SO. Given an objective function, the optimization process can be translated into a learning rule that is driving the SO process.

These OFs all fulfill the prerequisite of a principled approach to SO: as they are formulated in a domain invariant way, they do not determine specific directions for the autonomous development, avoiding to put in what one actually wants to get out. But this achievement creates a dilemma which is the second, more serious challenge to SO. In fact, and this seems to be the argument, if nothing is specified from outside, will SO simply make the robot an arbitrary subject that is completely unpredictable in its behaviors and thus rather a thread than a hope. The aim of this paper is to show that this attitude is not justified. Instead, we will develop an understanding of what happens if the system is self-organizing, what the role of the embodiment is and how we can find clues for predicting and shaping the behavior patterns emerging in a genuine SO scenario.

In this paper we study how a self-organizing approach to robot control can break symmetries of the robot-environment system such that structured behavior emerges. Our approach is based on a new learning rule, see Der (2013), applied to two robotic systems. By these examples, we want to make the reader aware of the phenomenon of spontaneous

symmetry breaking that is in our opinion instrumental for understanding how SO can be effective in robotic systems. We think that the robotic community so far has overlooked the importance and substance of that phenomenon. It is one aim of this paper to contribute to the dissemination of this prospective ingredient for modern embodied robotics, see also Pfeifer and Bongard (2006); Pfeifer et al. (2007).

This paper is organized as follows: The next section describes the control framework which is the basis for the definition of the unsupervised learning rule in the following section. Then we present the first robotic scenario in section “Vehicles: behavior as broken symmetry” with examples of behaviors from sparse symmetry breaking events. We formulate a “rule of thumb” for self-organizing behavior from symmetry breaking. It follows the section “The HEXAPOD” in which we study the emergent behavioral modes and control structures using a six-legged robot. Finally we conclude with a discussion. Supplementary material, especially videos, are available at <http://playfulmachines.com/ECAL2013>.

### Control Framework

Fundamental to our approach is the closed loop control setup. The controller of the robot is given by a one layer feed-forward neural network transforming sensor values  $x \in \mathbb{R}^n$  into motor values  $y \in \mathbb{R}^m$  as

$$y = K(x, C, h) = g(Cx + h) \quad (1)$$

where  $C$  and  $h$  are the parameters (synaptic strengths and bias values, respectively) and  $g_i(z) = \tanh(z_i)$  is the sigmoidal activation function. The translation between the external and the internal world can be done by a forward model predicting future sensor values on the basis of the current sensor and motor values. Here we use a linear network:

$$x_{t+1} = \phi(x_t, y_t) + \xi_{t+1} = Ay_t + Sx_t + b + \xi_{t+1}$$

where  $\xi$  is the prediction error and the parametrized function  $\phi : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$  is the predictor with the parameter matrices  $A$  and  $S$ , and the parameter vector  $b$ . The forward model can be adapted on-line by a supervised gradient procedure to minimize the prediction error as

$$\Delta A = \eta \xi y^\top, \quad \Delta S = \eta \xi x^\top, \quad \Delta b = \eta \xi. \quad (2)$$

In the applications, the learning rate  $\eta$  may not be small such that the low complexity of the model is compensated by a fast adaptation process. It is one message of this paper that, due to the strong interplay with the embodiment, these very simple control structures can produce amazingly complex behaviors.

### One-Dimensional Example

Let us consider a wheeled robot on a rail with a single motor and a single wheel-counter measuring the wheel velocity.

Connecting the simple controller given by equation (1) and interpreting the motor values as target velocities we can analyze the dynamical properties of the system. Let us first consider  $h = 0$ . For  $C < 1$  there exists only one fixed point for  $x = 0$ , corresponding to the standing robot whereas for  $C > 1$  there are two fixed points one for forward and the other one for backward driving. The system is fully symmetric in this respect assuming that also the morphology is perfectly forward-backward symmetric. More formally the system is invariant against inversion of the  $x$ -axis. For  $h \neq 0$  there is an asymmetry in the bifurcation structure, which we will not discuss further, see Der and Martius (2012) for details.

At this simple example we can understand how symmetries can be broken by noise. Let the controller be given by  $C = 0, h = 0$ , such that the robot is in total rest. When we now increase  $C$  to a value larger than 1 we cross the bifurcation point and the resting state becomes unstable and the perturbations by e. g. noise decide to which fixed point the system goes.

### Unsupervised learning for self-organization

In recent work, the so called predictive information (PI) was introduced as a general objective function for SO (Ay et al., 2008, 2012; Zahedi et al., 2010). In Martius et al. (2013), a modification of the PI, the so-called time-local predictive information (TiPI) was introduced for better coping with the problem of non-stationarity in continually learning systems. By maximizing the TiPI, a general learning rule for the synaptic strengths of a neural controller network was derived. Different from infomax principles derived so far, the method interrelates the principle formulated at the level of behaviors directly down to the synaptic level.

In Der (2013), starting from the learning rule given in Martius et al. (2013), a new rule was presented. Compared to the TiPI, this new rule was shown to drive the system toward self-organization in a more sensitive way, giving rise to a rich scenario of spontaneous symmetry breaking. This was argued to open ways to new classes of self-organized behavior. A discussion will be given below.

The rule is written as (all quantities are at time  $t$ )

$$\frac{1}{\varepsilon} \Delta C_{ij} = \delta y_i \delta x_j - \gamma_i y_i x_j \quad (3)$$

$$\frac{1}{\varepsilon} \Delta h_i = -\gamma_i y_i \quad (4)$$

where  $\delta x_t$  is the prediction error based on time  $t - 1$

$$\delta x_t = x_t - \phi(x_{t-1}, y_{t-1})$$

or some other perturbation quantity<sup>1</sup>.  $\delta y_t$  is defined in terms

<sup>1</sup>The new rule is not restricted to using  $\delta x$  as the prediction error. Instead we are free to consider  $\delta x$  as any convenient change in or perturbation of the sensor dynamics. In the experiments described below we used the change of the sensor values in one time step.

of the world model as

$$\delta y_t = J^\top \delta x_{t+1} \quad (5)$$

where

$$J = \frac{\partial \phi(x, y)}{\partial y}$$

is the Jacobian matrix of the forward model expressing the sensitivity of its output on the input  $y$ . In our linear model, we simply have  $J = A$ .

Moreover,  $\gamma_i$  is a neuron specific learning rate defined as

$$\gamma_i = 2\alpha \delta y_i \delta z_i \quad (6)$$

where  $\alpha$  is an empirical quantity controlling the sensitivity with  $\alpha > 1$ , and  $\delta z = C\delta x$  is the change in the postsynaptic potential caused by  $\delta x$ .

### Discussion of the learning rule: self-induced symmetry breaking

The specific form of the learning rule allows for a very basic interpretation. Let us start with the last term  $\gamma_i y_i x_j$  contributing to  $\Delta C_{ij}$  which is easily recognized as a Hebbian term since it is the product of the input  $x_j$  into the synapse  $C_{ij}$  and the activation  $y_i$  of neuron  $i$ . As such it would strengthen all paths in the SM loop for which there is a strong output of the motor neuron combined with a strong response from the outside world as reported by the sensor value  $x_i$ . This would drive the neurons into saturation. However, with the negative sign (and  $\gamma_i > 0$ , in standard situations), the term actually is anti-Hebbian, counteracting the saturation of the neurons.

The first contribution,  $\delta y_i \delta x_j$  is Hebbian again, formulated, however, not in the activations itself but in their deviations from the predicted values as generated by the model. Given the relation between  $\delta y_t$  and  $\delta x_{t+1}$ , see equation (5),  $\Delta C_{ij}$  is strengthened if there is a strong correlation between  $\delta x_{t,j}$  and the components of  $\delta x_{t+1}$  being fed by  $\delta y_{t,i}$ . Roughly speaking, in that way the first term in the learning rule tries to increase the propagation of perturbations  $\delta x$ , driving the system towards instability. Here we can draw a parallel to homeokinetic learning (Der and Martius, 2012), where we also have two antagonistic terms which together should drive the system towards an exploratory behavior. The structure of the learning rules are similar but differ in details, as discussed below.

In the bifurcation scenario discussed above, the symmetry breaking was induced by changing the controller parameter manually. With the unsupervised learning rule, we have a self-referential system, a dynamical system that changes its parameters by itself, see also Der and Martius (2012). The decisive point in this scenario is the fact that (i) the learning rule does not introduce explicitly any violations of symmetries of the physical system it is applied to, but that (ii)

Figure 1: The TWOWHEELED as a 3D physical object. The motor values are interpreted as wheel velocities, however the simulated motors have a maximal force. The ground is elastic so that the wheels sink into the ground depending on their load. Additionally there is friction and slip. The sensors measure the actual wheel rotation velocity. (A,B) wheel size 1: the robot is lying more or less flat on the ground when driving straight. When moving in a curve, there is an inclination due to the physical forces making the effective radius of the wheels different, see the video S1. Note the wheels are about 2% off center, so the robot is not fully forward/backward symmetric. (C) Wheel size of 1.2 the body can tilt to the front and back. These 3D effects would make both odometry and the execution of motion plans very difficult as they involve the full physics of the robot.

the learning drives the physical dynamics towards instability, eventually causing a **spontaneous** breaking of existing symmetries.

To give an example: consider a hexapod robot (see e. g. Figure 7 below) where the parameters  $C_{ij}$  represent the couplings between the sensors and the motors. Intuitively the  $\delta x$  and  $\delta y$  contain some information of the current mode of behavior, that is not already modeled perfectly by the forward model. Combined in the driving term the learning rule will amplify a latent (easy to excite) mode of behavior.

### Vehicles: behavior as broken symmetry

Let us now apply the new learning rule to the specific example of a TWOWHEELED robot (Figure 1) such that the characteristic properties of the self-organization process are illustrated. For the simulations the LPZROBOTS simulator (Martius et al., 2010) was used.

#### Least biased initialization

In applications, a first point is about the choice of the initial parameters of the networks and the initial configuration of the robot. With our specific choice of the controller network, the initialization with  $C = 0$  seems most natural because this corresponds to a controller that is completely numb, i. e. deprived of any functionality. Putting additionally  $h = 0$ , we find that all motor neurons send the command  $y_i = 0$  to the motors, independently of any inputs.

Choosing the initialization in the described way has different effects on the initial pose the robot is taking. For example, in the TWOWHEELED case this means that all wheels are held at rest (velocity control). In robots with

joint-position control,  $y = 0$  means that all joints are driven towards their center position.

The combined system, comprising the physical and the synaptic dynamics, is fully deterministic. If starting in the least biased initialization the combined system may be in an unstable fixed point. We can either add small noise to the sensors for a short time interval or position the robot initially such that sufficient perturbation occur. Without further noise, the actual initial condition is fixed and the time evolution of the entire system is deterministic.

### Symmetry breaking—a rule of thumb

Before going on to present the experiments, let us formulate a simple rule of thumb on the development of the robot when starting from the least biased condition: in typical experiments we observe that the behavior of the robot can be described as being active (caused by the driving term in the learning rule ( $\delta y_i \delta x_j$ )) while conserving as much of the original symmetries of the system as possible. When only few of the symmetries are broken we call it the parsimony (or economy) of symmetry breaking. Note that symmetries involve not only the geometry of the robots body but also all the symmetries of the physical dynamics. In the two-wheel robot case the body geometry is described by left-right and forward-backward symmetries. The physical symmetries are based on the robot being an object in space and time, the physics being invariant against both translations and rotations of the frame of reference, taking however account of the physical boundaries (objects, walls, and ground). To give an example: If the robot drives in a straight line back and forth, the rotational symmetry of the space is broken, whereas the forward-backward, left-right symmetries are conserved. However, if the robot drives in a circle the rotational symmetry is conserved and the others are broken. So a 'good' behavior in the sense of parsimoniously broken symmetries would be driven in a circular pattern with both forward and backward driving.

Let us also emphasize that symmetry breaking observed in this scenario is emerging as a phenomenon “from inside” the deterministic system itself so that we may speak of a spontaneous symmetry breaking (SSB). As an additional feature, the breaking of the symmetries can largely be influenced by external impacts (physical forces in the sense of a desired mode) and/or by choosing specific sensor combinations that help to organize the symmetry breaking scenario. We will give an example with the HEXAPOD further below.

### Results

The learning starts in the least biased way, so that the symmetry breaking should follow the principle of parsimony mentioned above. In particular, the physical system is invariant against spatial transformations, i. e. translations or rotations of the spatial frame of reference. With the constraints given by the (elastic) surface, the remaining symmetry oper-

Figure 2: Deterministic trajectories of the robot in the ground plane emerging with different learning rates  $\varepsilon$ . If learning is fast ( $\varepsilon > 0.01$ ), irregular trajectories occur (A). With lower rates (here  $\varepsilon = 0.001$ ), after a transient phase of irregular motion through metastable attractors (B), the dynamics is converging toward a limit cycle behavior (C), called the master cycle below. The width of the robot is displayed by the small scale-line at the bottom. See also video S2. Parameters:  $\alpha = 3$ .

ations are rotations around the  $z$  axis and translations in the  $x - y$  plane. Remember that the learning rule gives no clue of how symmetries are to be broken.

When using the controller (equation (1) with the learning dynamics given by equations (3) and (4) (and fixed forward model with  $A = \mathbb{I}, S = 0, b = 0$ , for simplicity), we expect the robot to start moving after some time<sup>2</sup> while trying to conserve as much of the original symmetries as possible. However, when using a learning rate  $\varepsilon$  above a certain value, the robot is seen to engage in a sequence of left and right turns combined with motions back and forth along curved lines, without any regularity to be seen, see Figure 2(A). Still, note that these trajectories are fully deterministic. Nevertheless, our rule of thumb obviously is not valid in this regime as there is no visible footprint of the underlying symmetries—the invariances against rotations and translations of the physical space.

The situation changes drastically when using smaller learning rates so that the interplay between learning and physical state dynamics is given time to unfold. Figure 2(B,C) is demonstrating a typical behavior of the robot. After starting, the robot is running through a kind of metastable patterns converging after some time toward a

<sup>2</sup>When using low learning rates, this time can be very long so that we often start the robot with an initialization close to the bifurcation point, choosing  $C = c\mathbb{I}$  with  $c$  close to 1. Contrary to the HEXAPOD treated below, in the TWOWHEELED case, no substantial differences in the behaviors were observed.

Figure 3: The circular pattern formation (Figure 2(C)) is hidden in the dynamics of the controller parameters as driven by the general learning rule. The  $C$ -matrix (A) is seen to be of a nearly perfect  $SO(2)$  structure (rotation matrix), which can be described by a single rotation angle and a scaling, so instead of four parameters there are only two required. The  $h$  dynamics is seen to be periodic with a slight bias. (B) the two sensor values (wheel velocities).

Figure 4: Patterns for frozen controller parameters occurring along the master cycle, Figure 2(C). Depicted is a selection of such patterns from parameter snapshots in one period of the state-parameter dynamics (about 200 time steps in Figure 3). If the learning is switched on again, the full dynamics is converging back to the master cycle.

large scale circular pattern (CP).

The parameters of the controller during the CP (Figure 2(C)) are not constant but run themselves through a limit cycle as displayed in Figure 3. This is an immediate consequence of the close and persistent coupling between learning and physical dynamics. What happens if we keep them fixed at any time? The answer is quite astonishing: a variety of different patterns emerges, as displayed in Figure 4. This also illustrates that the parameter dynamics within the limit cycle is actually important for the particular pattern. The former can be seen as a transient along the many stable patterns with fixed parameters. Upon switching on learning again, the system rapidly returns to the original CP (with a different spatial position). This so called pattern spin-off effect was for the first time reported in Der (2013), this paper presents additional results demonstrating the richness of that phenomenon.

At present we do not have a complete microscopic un-

Figure 5: The emerging patterns also depend sensitively on the learning parameters. The figure shows the emerging patterns with changing  $\alpha$  parameter (from left to right) as  $\alpha = 1.0, 1.3, 1.9, 2.0$ .

A B

Figure 6: The role of embodiment. (A) Wheel size 1.1 (default 1.0). After a very irregular initial phase, the robot enters an aligned wiggly pattern, running at first to the right and then back toward the left lower corner. (B) Wheel size 1.125 leads to a circular pattern again. Parameter:  $\varepsilon = .001$ ,  $\alpha = 3$ .

derstanding of the effects. Still, at the level of phenomena, there is a number of observations. One is that the very nature of the emerging patterns depends in a most sensitive and intricate way on both the embodiment and the learning dynamics. For instance, by varying the so called sensitivity parameter  $\alpha$  (equation (6)) of the learning rule we obtain a set of quite different CPs as shown in Figure 5.

Alternatively, we may change the embodiment and obtain another class of behaviors. One option is to increase the wheel size that causes the trunk of the robot to tilt more when accelerating, see Figure 1. Two exemplifying trajectories are presented in Figure 6. For certain wheel sizes we may get also linear patterns, as they are predominant with a fully forward/backward symmetric robot. On the general level we may argue that for the linear pattern not the rotation symmetry is partially conserved, but the translational one along the line. However only a small change in the wheel size yields a CP again but with a very different fine structure.

Are we lost? Confronted with such an overwhelming variety of emerging patterns, are we faced with a robot that is behaving completely unpredictable confirming just the concerns against self-organizing robots we wanted to dispel? One answer is found by taking a look at the controller parameters. As Figure 3 shows, the controller matrix  $C$  is of a very specific structure, it is a nearly perfect (scaled) rotation matrix. Any such matrix rotates a vector by an angle and stretches it by a factor, so it is parametrized by only two

Figure 7: The HEXAPOD. 18 actuated DoF: 2 shoulder and 1 knee joint per leg. Fully forward/backward and lateral symmetric.

variables. This specific structure of the controller matrix, obtained by the learning, also seems to be responsible for the specific pattern creation effects. In principle, there are essentially three possibilities for the asymptotic system dynamics with a fixed controller matrix: fixed point, limit cycle and chaotic attractor. As we have observed in a series of experiments, the limit cycles are most likely to occur with a rotation matrix. This is intuitively understandable given that the physical space is invariant against rotations.

In a sense, this specific controller structure is like a footprint left by the symmetries of physical space, imprinted into the controller by **spontaneous** symmetry breaking, driven by the unsupervised learning procedure that does not break any symmetries by itself.

So, from looking inside, there is a coarse explanation of how the robot achieves the patterns—by discovering, so to say, the world of rotation matrices. However, the point of major interest is that the learning finds those specific structures. On a general level, an understanding may be given by the rule of thumb: a pattern in space can only emerge from breaking the spatial symmetries inherent in the physics of the robot. When trying to make this symmetry breaking as parsimonious as possible, a circle is nearly perfect: while it has broken the translational symmetry (the center is a fixed point in space), rotation symmetry (around that center) is fully conserved. Yet, because of its fine structure, the actual patterns emerging in the learning scenario are not circles but CPs. Nevertheless, they are still invariant against rotations about a definite angle, see in particular the patterns of Figure 4 and Figure 5. This may be seen as a noteworthy parallel to the hexagonal patterns known from many phenomena in nature. So, the observed patterns apparently are the ones with a high degree of preserving the spatial symmetries of the physical system.

### The HEXAPOD

Let us now follow the trace of symmetry breaking with a high-dimensional six-legged robot: the HEXAPOD, see Figure 7. We choose this robot because it will be seen to reveal symmetry breaking phenomena in a particularly clear way. The robot has six legs, each one with three degrees of freedom (DoF). Each of the 18 joints is actuated by a servo mo-

Figure 8: Initially, after about 20 min the robot develops a swaying motion pattern (top row), as if it is very actively trying to move the legs in a coherent way while keeping ground contact. 50 min later a raising behavior develops where the trunk is repeatedly being lifted from the ground.

tor and contains a sensor that is measuring the actual joint angle. The effective torques acting on the joint axes are determined by a PID controller with a limited force. To enable a body feeling (some useful feedback from the interaction), this force limit is proportional to the deviation from the set point, such that there is an elastic reaction to external forces, similar to a system controlled by muscles.

In a typical experiment, the HEXAPOD is falling down from a starting position a little above the ground. With the least biased initialization the motor values are zero ( $y = 0$ ) so that all joints are in their center positions. When hitting the ground, the robot gets into a damped vertical oscillation due to the elasticity of the joint-motor system. This is sufficient for providing an initial perturbation  $\delta x$  that is further amplified by the learning dynamics.

What can we expect to happen? Depending on the concrete situation (e.g. particular  $\varepsilon$ ) different behaviors may emerge. In most cases the robot starts with a swaying motion pattern, see Figure 8 and video S3. We may claim again, that this is in agreement with our rule of thumb since in this motion the joint angles are changing with a pretty high degree of coherence as allowed by the physical constraints enforced by the ground contacts.

More interesting behaviors emerge after some time, for instance a raising behavior, see Figure 8. The entire development can be followed in short pieces in the videos S3-S6. There is another surprise—when looking at the parameters of the controller. In the *TWO WHEELED* case the *C*-matrix developed into a rotation matrix. Of course, we can not expect such a clear result in the case of our HEXAPOD because of the much higher dimensionality of the physical space and the interaction with the ground.

Yet, as Figure 9(A) shows, the emerging sensor-to-motor coupling matrix is highly structured, reflecting the original symmetries to a high degree. Both the shoulders vertical direction and the knees are seen to follow essentially the same strategy for moving the body. This is in agreement with our rule of thumb since this collective strategy allows the body to be moving, but with a maximum degree of coherence between the individual constituents of the body. Moreover, the coupling matrix reveals the whole-body nature of the behavior—the control for each body part is generated by

Figure 9: The parameters of the controller ( $C$ -matrix) for two scenarios. Element  $C_{ij}$  represents the coupling from sensor  $j$  to motor  $i$ . Indices: 1-12: shoulders (vertical/horizontal), 13-18: knees. (A) Swaying motion, Figure 8. (B) Seesaw motion with velocity sensor (index 19), see Figure 10. The difference between the swaying and seesaw behavior are clearly visible in the structure of the matrices. While in swaying all legs follow the same strategy, the antiphase nature of the seesaw behavior is reflected in the different sign distribution of the matrix elements.

Figure 10: Seesaw motion pattern with forward/backward speed sensor (top row), see video S7. Jumping motion pattern emerging with vertical speed sensor (bottom row), see video S8. Note the robot is in the air in the frames 2-4.

combining both excitatory and inhibitory signals from the sensors of all joints in a systematic manner.

### The formative power of exteroceptive sensors

Up to now we were using only proprioceptive sensors so that the orientation of the robot in space can only be measured very indirectly, e.g. by additional load to the joint motors due to gravity forces. By including exteroceptive sensors, the development of the modes can be influenced and driven into desired directions. Adding a sensor measuring the forward velocity of the robot generates a seesaw motion. In contrast, a sensor measuring the vertical velocity of the robot leads to a pronounced jumping behavior, see Figure 10. Also here, we find highly structured controller matrices, see Figure 9(B) for the seesaw case. Note the strong coupling of the exteroceptive sensor to the motor neurons showing the functional role of that sensor. It distinguishes forward and backward motion and thus this symmetry is lost, so that in the learning process behaviors with broken forward-backward symmetry are favored.

## Discussion

This paper tries to answer essentially two questions. The first question is about how to organize self-organization, in other words, how can we find intrinsic mechanisms that

make a system able to self-organize. The answer was given by the unsupervised learning rule (ULR), see equations (3) and (4), which fulfills the main criterion for a genuine SO: it is universal in the sense that the only necessary information about the system is given by the number of sensors and that of motor neurons, any further information being acquired by the co-learning self-model in a bootstrapping process.

The second question we want to answer in this paper is suggested by exactly that bootstrapping scenario: with nothing specified from outside, what can we expect the learning system to do. What will the emerging behaviors look like and what will the relation to the embodiment of the robot be? How and to which extent are the emerging behaviors determined by the embodiment; and can we find systematic criteria for those behaviors?

Several answers could be given by looking into the role of the underlying symmetries of the system in space and time which induces, given the constraints, corresponding symmetries in the physical system. The point then is that, while driving the system towards instability, the ULR is preserving these symmetries. As a result, the evolution of the system in the learning process is realized by a sequence of spontaneous symmetry breaking steps, following—similar to what we know from nature—a kind of parsimony principle. This leads to our rule of thumb: the emerging behaviors in physical systems (robots) driven by our ULR are qualified by a high activity while preserving as much of the underlying symmetries as possible.

This rule brings the embodiment to the foreground. The symmetries are embodiment specific and, moreover, breaking the symmetries is a process that is related to the very physics of the system. This was demonstrated by a number of examples. The first and probably the most surprising one was given by the TWO WHEELED robot. Controlled by two neurons with a fast synaptic dynamics given by the ULR, the system in many cases was converging towards a limit cycle behavior with the trajectories of the robot forming nearly perfect geometric patterns. The emerging geometric patterns were seen to depend on the embodiment (like the wheel size) in a very intricate and sensitive way. Interestingly, the limit cycle acts as a pattern factory: the parameters occurring along the limit cycle produce a great variety of spin-off patterns. While this effect has already been reported in Der (2013), this paper presents further results and gives additional insights into this interesting effect.

Continuing the work started in Der (2013), similar effects of symmetry breaking were obtained in the example of the HEXAPOD. We observed the excitation of body related, high activity modes with a high degree of coherence between the body parts. These modes were argued to be in nice agreement with our rule of thumb: emerging behaviors are qualified by high activity while preserving the underlying symmetries of the system as far as possible (the principle of parsimony in spontaneous symmetry breaking). In future work

we will be looking for a parallel of the pattern spin-off effect, hoping to thereby uncover a kind of pattern factory for these more complex systems, too.

These results are a step forward as compared to the state of the art. Previous work in self-organizing robot behavior was either restricted to small, easy to analyze systems or produced—like with the principle of homeokinesis—behaviors which looked interesting and were often completely surprising (Der and Martius, 2012), as it should be. However, by the same argument, it was often not clear what the robot is actually doing. With the new learning rule and the concept of behaviors as broken symmetries, this is now (a little) different. The essential difference between homeokinetic learning and the ULR is the dynamics with the least biased initialization (“do nothing” region with all synapses zero). While the time-loop error of homeokinesis has a pole there, the infomax based objectives are smooth in that region. It is basically this smoothness that makes the learning to integrate the responses of the system dynamics in a sensitive way. As compared to the TiPI (Martius et al., 2013), the learning dynamics used here is even smoother and even more concentrated on system responses which explains the prevalence of spontaneous symmetry breaking effects. At a more formal level, we see the difference also in the drift of the local Lyapunov exponents: while homeokinesis drives small exponents stronger than larger ones, the situation is inverted in the present learning dynamics. Given the formative interplay between state and learning dynamics, this has important consequences for the emergence scenario of the behaviors.

The principles and examples given in this paper—in particular the emergence of coherent modes, the TWO-WHEELED as a pattern factory and the various modes realized by the HEXAPOD—may help us to better understand and exploit the synergy between embodiment and SO of autonomous robots.

## Abstract

This paper presents a novel and bio-inspired algorithm for distributed division of labour in swarms of artificial agents (e.g., autonomous underwater vehicles). The algorithm is inspired by division of labour via local interactions in social insects. The algorithm is successfully implemented in virtual agents and simulated robot swarms and demonstrates a high adaptivity in response to changes in the workforce and task demands in the swarm level as well as a high specialization to tasks in the agents level.

## Introduction

In the field of swarm intelligence and collective robotics, social insects are promising sources of inspiration due to their capabilities in self-organization and self-regulation in the colonies. Division of labour is one of the prominent characteristics of social insects such as honey bees (Seeley (1982); Huang and Robinson (1992)) and ants (Hölldobler and Wilson (2008); Julian and Cahan (1999)). The insect colonies maintain plasticity that adapts the division of labour to the status of the colony and, in parallel, also to environmental situations, e.g. to the number of workers or task-demands. The flexibility and quick response to the changes in the status of the colony and environment in one hand and specialization of workers for the tasks in the other hand are interesting properties of the methods driving behaviour in the colonies.

Several models have been proposed to explain the mechanisms of division of labour in social insects, e.g. foraging-for-work (Tofts (1993)), response-threshold reinforcement (Bonabeau et al. (1997); Theraulaz et al. (1998)), and common-stomach models (Karsai and Schmickl (2011)) (for a good review of such models see Beshers and Fewell (2001)). These models have been also used as inspiration for distributed algorithms in application areas such as swarm robotics. For example, in Gross et al. (2008) and Labella et al. (2006), models of ants-foraging behaviour have been implemented for maintaining division of labour in a group of robots performing an object retrieval task or response-threshold reinforcement model (Bonabeau et al.

(1997); Theraulaz et al. (1998)) that is inspired by wasps is applied for swarms of robots (e.g. in White and Helferty (2005); Yang et al. (2009)), or in Schmickl et al. (2007) a *trophallaxis-inspired* strategy which is inspired by food exchange of honeybees and ants is applied to a simulated robot swarm.

In this paper, we are interested in a mechanism of division of labour that is inspired by behaviours of honey bees (Huang and Robinson (1992, 1999)). A honey bee undertakes different tasks during its life-time in a process of behavioural development. In earlier weeks of its adult life, a honey bee performs nursing, then it performs other tasks inside the hive, and only in its final weeks it leaves the hive for foraging (Johnson (2010)). This behavioural development can be delayed, accelerated, or even reversed in response to changes in colony or environmental conditions. *Social inhibition* is proposed (Huang and Robinson (1992)) as a conceptual method for maintaining this adaptive behaviour of the colony. In this method, tasks are considered in an ordered sequence. The behavioural development of an individual that determines when the worker switches to the neighbouring task in the sequence is regulated via local interactions with other individuals.

In this paper, a distributed algorithm of division of labour based on local communication is inspired by social inhibition. The algorithm considers the spatiality of the task-regions that restrict the possible local interactions between the individuals as it is more realistic regarding many application areas and also the biological system. For example, in a honey bee colony, the workers of the tasks which are early in the sequence stay inside the hive while the workers of the tasks later in the sequence work outside the hive. The very early workers do not have much contact with the out-of-the-hive workers. In other words, the interactions are restricted to some extent to the individuals of the tasks which are next to each other in the sequence.

Despite the biological source of inspiration of the proposed algorithm, we aim for applications in swarm robotics. In particular, where there is a spatial clustering of the robots based on their tasks that limits the local communications

to the robots of the same or neighbouring tasks. The proposed algorithm is simple and easy-to-implement. It is implemented in swarms of virtual agents as well as swarms of simulated robots that perform several tasks. The behaviour of the swarm in response to the changes in the number of agents in each task and the task-demands are investigated representing adaptability that is achieved by the algorithm.

### Social Inhibition

In honey bee colonies, division of labour is mainly based on the age of the workers. This mechanism is called *temporal polyethism*. In temporal polyethism, there is a correlation between the age of the workers and the tasks they perform; e.g. older workers perform tasks outside of the hive and younger workers perform tasks within the hive (Wilson (1971); Robinson (1992)). The behavioural development of the bees is associated with their physiological development such that the physiological age of a bee indicates the main task that it performs (Winston (1987); Beshers et al. (1999)).

As it is shown in different studies (e.g. Huang and Robinson (1996)), honey bee colonies are flexible to changes in age distribution of the colony and task demands. For example, in a colony of young honey bees, the age in which a bee starts foraging (an outside task) is lower than in a normal colony. It means the behavioural development in such colony is accelerated. On the other hand, presence of older bees delays or inhibits the development of physiological age of other bees in the colony. Another example is the behaviour of the colonies when the hive workers are removed. In this case, the development of physiological age decreases and inverts resulting in transformation of out-of-hive workers into inside-the-hive workers.

Huang and Robinson (1992) proposed that worker-worker interactions drive mechanisms of hormonal regulation in bees resulting in a social inhibition that explains temporal polyethism and adaptability of the colony to different age distributions. The concept is then used in other researches toward developing models of social inhibition, e.g., Beshers (2001); Naug and Gadagkar (1999); Gadagkar (2001). In this work for some reasons Naug and Gadagkar (1999); Gadagkar (2001) are not used as a source of inspiration.

### Previously Suggested Algorithm: Evolution Maps

One of the models of social inhibition following Huang and Robinson (1992) is the model of *evolution maps* proposed by Beshers (2001). In this model, a “map” which is a set of curves describing changes in the physiological age of the individual is introduced. A state variable  $x$  represents the physiological age of every individual. In addition to that, the individuals also contain an auxiliary variable  $y$ . In every time-step (day for bees), an individual has a number of interactions with others.  $y$  is a weighted average of  $x$  values of all the interacted individuals. The weights are set based on the task the individual is performing. Every curve of the

“map” describes changes of  $x$  based on its current value and the value of  $y$ .

In the reported work (Beshers (2001)) two tasks are implemented. A threshold is set to indicate which task is chosen by the individual based on its  $x$  value. The threshold is augmented with higher and lower margins providing more stability for the system. The curves are derived based on experimental data from real bees.

Although the model might be extendible to more tasks, global-range interactions (interactions between individuals irrespective to the task they are performing) would be a necessary condition for the stability of the model. The reason is that if the interactions are restricted, e.g. to the neighbouring tasks in the task-sequence, the  $y$  value is no longer an estimation of the  $x$  in the whole system and will have instantaneous changes when an individual switches between two tasks leading to endless back and forth switchings.

Apart from the complexity of generating a proper map, the global-range interaction is usually not the case in both insects and robotic tasks, since workers of different tasks are usually separated spatially and interactions are restricted to individuals of the same or neighbouring tasks.

### New Proposed Algorithm

One of the properties that we are interested in them are the ability of the decentralized algorithm to divide the swarm into groups relative to the task-demands while the system is flexible to changes in the demands and workforce. In addition, the number of switchings between different tasks should be limited due to practical costs (e.g., a robot may need to spend some energy to change its working area in order to perform a different task). Therefore, specialization of the individuals is also of our interest.

In the proposed model, every individual contains a state variable  $x$  as its physiological age. This variable is restricted to a defined range of  $(x_{min}, x_{max})$ . There is a number of tasks with their associated demands. The tasks are ordered in a sequence such that an individual can only switch to the previous or the next task in the sequence.

An individual chooses a task based on its  $x$  and a set of defined thresholds that separate the tasks (see Figure 1). The thresholds are used together with lower and upper margins. For an individual that is performing  $task_i$ , in order to switch to  $task_{i+1}$ , its  $x$  value should exceed  $th_{i:i+1} + upper\_margin$ . For an individual that is performing  $task_i$ , in order to switch to  $task_{i-1}$ , its  $x$  value should become lower than  $th_{i-1:i} - lower\_margin$ . The lower and upper margins prevent the individuals from instant back and forth switches between two consecutive tasks due to noisy changes in  $x$ .

The main idea of the algorithm is to spread the  $x$  values of the whole swarm uniformly over the range of  $(x_{min}, x_{max})$ . With such a uniform distribution of  $x$  throughout the swarm and setting the thresholds such that the range is split into segments relative to the task-demands, the required number

Figure 1:  $x$  changes with small steps in a range of  $(min_x, max_x)$ . A task is assigned to the individual when its  $x$  variable passes the respective thresholds.

Figure 2: An example uniform distribution of  $x$  and proper thresholds that split the range relative to the task-demands. In this example, eight agents are divided into three tasks. The relative demands for the three tasks are 25%, 50%, and 25% respectively.

of agents will be assigned to each task (see Figure 2).

Regulation of  $x$  values in the swarm occurs through local interactions between the individuals. Every individual contains two variables that keep track of its experience in the swarm. In an ideal case, these two variables stand for the closest higher and lower  $x$  values belonged to other individuals in the swarm. In practice, these variables have to be estimated during interactions. Let these variables be  $x^{low}$  and  $x^{high}$ . In the ideal case their variables are as follows:

$$\begin{aligned} x^{low} &= \arg \min_{x_i} (|x - x_i|), \text{ where } x_i < x \\ x^{high} &= \arg \min_{x_i} (|x - x_i|), \text{ where } x_i > x \end{aligned} \quad (1)$$

The value of  $x$  is updated for each agent in the direction towards the average of its  $x^{low}$  and  $x^{high}$ , as follows:

$$x = \begin{cases} x + \delta & \text{if } x - x^{low} < x^{high} - x \\ x - \delta & \text{if } x - x^{low} > x^{high} - x \\ x \pm X & \text{otherwise} \end{cases} \quad (2)$$

where  $\delta$  is *step-size* which is a constant parameter with a small value in terms of the size of segments for every task. In the current implementation  $X \sim \delta \times U(0, 1)$ .

Since there is no global information about the  $x$  values in the swarm, agents update their  $x^{low}$  and  $x^{high}$  values gradually during time and in every interaction with another agent.

Say agent  $i$  interacts with agent  $j$ .  $x^{low}$  and  $x^{high}$  are updated as follows:

$$x_i^{low} = \begin{cases} x_j & \text{if } x_i^{low} < x_j < x_i \\ x_i^{low} & \text{otherwise} \end{cases} \quad (3)$$

$$x_i^{high} = \begin{cases} x_j & \text{if } x_i < x_j < x_i^{high} \\ x_i^{high} & \text{otherwise} \end{cases} \quad (4)$$

$x^{low}$  and  $x^{high}$  also slowly drift away from  $x$  in every time-step in order to be adaptable to changes in other agents'  $x$  values as well as the environment:

$$\begin{aligned} x_i^{low} &= x_i^{low} - \varphi \\ x_i^{high} &= x_i^{high} + \varphi \end{aligned} \quad (5)$$

where  $\varphi$  is a value smaller than  $\delta$  in Eq. 2.

After every update of  $x$ , an individual considers switching to the previous or next tasks in the task sequence. For an individual with  $task_i$ , *new\_task* is chosen as follows:

$$new\_task = \begin{cases} task_{i+1} & \text{if } x > th_{i:i+1} + l_u \\ task_{i-1} & \text{if } x < th_{i-1:i} - l_b \\ task_i & \text{otherwise} \end{cases} \quad (6)$$

where  $th_{i-1:i}$  and  $th_{i:i+1}$  represent the threshold values between  $task_{i-1}$  and  $task_i$ , and  $task_i$  and  $task_{i+1}$  respectively.  $l_u$  and  $l_b$  are the upper and lower margins for the thresholds.

**The Algorithm** The following actions are performed by any agent  $i$  in every time-step of running:

1. update  $x^{low}$  and  $x^{high}$  using Eq. 5.
2. if there is an interaction with agent  $j$ :
  - (a) update  $x^{low}$  and  $x^{high}$  using Eq. 3 and Eq. 4.
  - (b) update  $x$  using Eq. 2.
  - (c) update the assigned task using Eq. 6.

## Experiments

A number of experiments are performed in order to investigate the performance of the proposed algorithm, its adaptivity to changes, and specialization of the agents to the tasks.

In the first set of experiments a swarm of virtual agents is simulated and the interaction between the agents performing the same task or in the adjacent tasks occur based on defined probabilities. The sensitivity of the algorithm to the chosen values for the step-size  $\delta$  is also investigated.

In the second experiment, a simulated swarm of moving agents (robots) is investigated and the interactions are based on the location of the agents in the arena in every time-step of the simulation.

### Virtual swarm experiments

The algorithm is first tested in a number of virtual swarms of agents.

In all of the following experiments a sequence of five different tasks is considered. Every experiment is repeated for

25 independent runs. Every run is simulated for 50000 time-steps while each agent runs the proposed algorithm. Interactions are possible between the agents of the same task or neighbouring tasks. In every time-step of the simulation, 30 interactions are sampled from a uniform distribution over all the possible interactions. All the agents are initialized by  $x_{min}$  for the state variable  $x$ . Experimental settings of the algorithm are represented in Table 1.

**Investigation of the algorithm with fixed settings** In the first experiment the demands for the five tasks are equal. The progress of the number of robots in each task over time is represented in Figure 3 (left). Since the agents start with the same initial value for  $x$  ( $x_{min}$ ), they all start with *task1*. By occurring interactions during time the  $x$  values are spread in the range and the swarm is split for performing different tasks.

In the second experiment the demands for the five tasks are 10%, 40%, 10%, 30%, 10% respectively. Figure 3 (right) represents the results.

All the runs reached the stable desired status for both experiments. The experiments were also repeated while the possible interactions between the agents of neighbouring tasks were limited to a fraction of the agents in each task instead of the whole agents and similar results were achieved (data not shown).

#### Investigation of adaptivity to changes in task-demands

In order to investigate adaptability of the swarm to changes in the task-demands, another experiment is performed starting with equal demands for every task. The task demands are then changed at time-steps 20000 and 40000.

Figure 4 (left) represents the results for this experiment. As the figure demonstrates, the swarm immediately reacts to the changes in the demands. The reason is that the  $x$  values of the swarm are spread almost uniformly in the range (in the ideal situation they are spread uniformly). By changing the task-demand, the thresholds over the range of  $x$  are changed such that the range is split relative to the new settings. Therefore, proper fractions of agents are reassigned for different tasks while the  $x$  values do not need to change.

#### Investigation of adaptivity to changes in work-force

In the next experiment the adaptability of the swarm to the changes in the number of agents presented in each task is investigated. In order to do that, the experiment starts with a swarm of 30 agents. In time-step 15000, 20 agents including all the agents in *task2* and *task3* are removed from the swarm. Later on in time-step 30000, 10 more agents are introduced in the swarm in the *task1*.

Figure 4 (right) represents the behaviour of the swarm in response to these changes. As the figure demonstrates, the swarm reacts to these changes by switching the tasks of the proper number of agents. The mechanism behind this reaction is as follows: When a number of agents are removed

from the system (or new agents are introduced), the uniformity of the distribution of  $x$  in the swarm is violated. The agents with  $x$  values close to the low-density (or high density) regions in the distribution react to this situation by shifting their  $x$  value towards the region (or in opposite direction). The process continues until the distribution becomes uniform again.

**Investigation of specialization** In order to investigate specialization of the agents for the tasks in the swarm, the number of non-necessary task-switchings of every agent is evaluated during the run-time. The settings are the same as the first experiment: fixed equal demands for all the five tasks. Since all the agents start with *task1* due to initial value for  $x$ , a certain number of switchings from a task to the next one is necessary for a certain number of agents. Moreover, any switching to a previous task (switch-back) is not desirable. Figure 5 represents the frequency of switch-backs during 50000 time-steps for all runs and agents for different values of step-size ( $\delta$ ).

**Investigation of the effects of step-size** The step-size  $\delta$  in Eq. 2 is a predefined parameter in the current implementation of the algorithm. Therefore, the sensitivity of the algorithm to this parameter is investigated by repeating the first experiment with different values for  $\delta$ . Figure 6 represents a comparison for different values. The main figure demonstrates the median error of the task allocation (number of agents in wrong tasks) over time. The inline figure compares the time required for reaching a swarm-state stabilized in maximum of 5% error.

As it is represented in Figure 6, for very small values of  $\delta$ , error decreases slowly. It is more quick for middle values. For high values of  $\delta$ , the error decreases quickly regarding the main figure, but regarding the inline figure the time to reach the stable status with maximum of 5% error is high. In addition, the sizes of quartiles are big indicating that in different runs different values are calculated for the time-to-reach. The instability of the high values is also visible in Figure 5 that represents the frequency of switch-backs for different  $\delta$  for all the runs during 50000 time-steps. In this figure, for  $\delta = 0.01$  there was not a single switch-back in all the runs. As  $\delta$  increases, the frequency of switch-backs also increases. In short, if the step-size ( $\delta$ ) is too small, the system is less reactive, and convergence takes longer. But if the value is too big, the system gets instable and results differ from case to case.

#### Simulated robot experiment

In this experiment a simulated robot swarm running the proposed algorithm is investigated for its behaviour and adaptability to the changes in the workforce and task demands.

A square arena is set up with a light source located in one side (see Figure 7). A swarm of robots is supposed to be split

Figure 3: Medians of the number of agents in each task over time for 25 independent runs. All of the runs reached the stable solution for both experiments. Tasks are represented by  $t_1$ ,  $t_2$ ,  $t_3$ ,  $t_4$ ,  $t_5$ . The left figure represents five tasks with fixed equal demands. The right figure represents five tasks with fixed demands of 10%, 40%, 10%, 30%, 10% respectively. Number of agents in both experiments are 30.

Time	0	20000	40000
$th_{1:2}$	20	10	10
$th_{2:3}$	40	50	20
$th_{3:4}$	60	60	30
$th_{4:5}$	80	90	60
Swarm Size	30	30	30

Time	0	15000	30000
$th_{1:2}$	10	10	10
$th_{2:3}$	50	50	50
$th_{3:4}$	60	60	60
$th_{4:5}$	90	90	90
Swarm Size	30	10	20

Figure 4: Medians of the number of robots in each task in 25 runs. All of the 25 runs reached the solution for both experiments. In both experiments the swarm starts with 30 agents. The left figure represents changes in the demands in time-steps 20000 and 40000. The right figure represents changes in the number of robots. In time-step 15000, 20 agents including all the agents in second and third task and randomly chosen agents are removed from the system. In time-step 30000, 10 agents are added to the system in the first task.

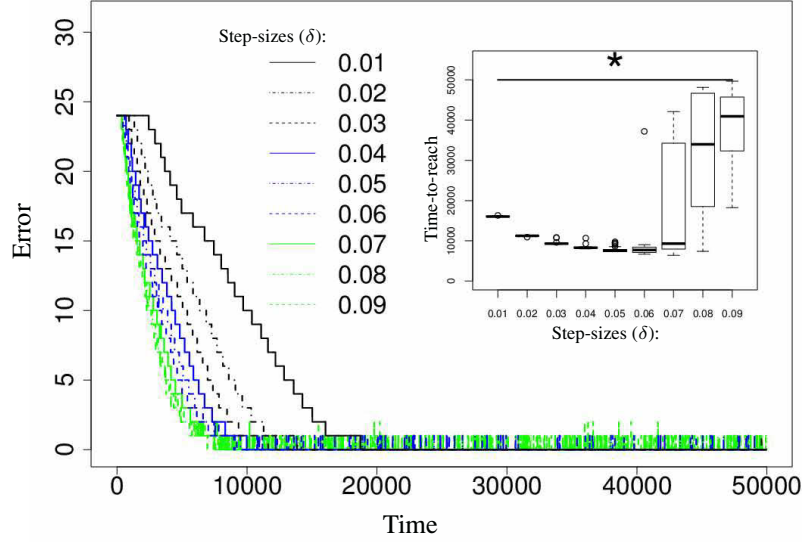

Figure 6: Comparison of error over time and also time-to-reach the stable status for nine different values of step-size  $\delta$  based on 25 independent runs. Main figure represents the median of the number of agents in wrong tasks (errors) over time for 25 runs. Inline figure represents the boxplots of the time to reach a swarm state that is stable with maximum one error out of 30 agents (more than 95% correct task-assignment) (\*: $p < 0.01$  for all pairs of  $\delta$  except (0.01,0.07) where  $p < 0.25$ ; Wilcoxon signed-rank test, unpaired data, "two.sided"-hypothesis). Box-plots indicate median and quartiles, whiskers indicate minimum and maximum, circles indicate outliers.

Table 1: Experimental settings for the proposed social inhibition algorithm

	virtual scenarios	robot scenario
$x_{min}$	0	0
$x_{max}$	100	100
$\delta$	0.03	0.1
$\varphi$	$\delta/30$	$\delta/3$
$l_u, l_b$	1	1

Figure 5: Frequency of number of switch-backs in 50000 time-steps for all the 30 agents and 25 runs. The figure represents the frequency for different values of step-size  $\delta$ .

up into three regions of the arena in order to cover the arena with different densities. Every robot has a luminance sensor perceiving the brightness of the light sensor. The three regions are located in different distances from the light source and the robots identify them based on their brightness. Each robot is able to rotate or move forward. When a robot decides to switch the task, it moves uphill or downhill the luminance gradient until it reaches the appropriate working region. Robots move randomly in their working region and do not leave it unless they decide to switch the task. A robot can interact with another robot which is located in its communication range by exchanging the  $x$  values. The arena is of size  $32 \times 32$  and the communication-range is five times bigger than the robots diameter.

Every robot  $i$  in the simulation performs the following:

- If the robot is in the region of its assigned task:

- Perform a random walk inside the task-region.
- Otherwise (the robot is out of its task-region):
  - turn towards the proper task-region based on the brightness gradient and step forward.
- regulate the state variables:
  1. update  $x^{low}$  and  $x^{high}$  using Eq. 5.
  2. if there is a robot  $j$  in the communication range:
    - (a) update  $x^{low}$  and  $x^{high}$  using Eq. 3 and Eq. 4.
    - (b) update  $x$  using Eq. 2.
    - (c) update the assigned task using Eq. 6.

At the beginning of the experiments, the number of robots is 16 and the task-demands are 25%, 50%, and 25% respectively which means 4, 8, and 4 robots are desired for each task-region. At time-step 20000, all the 8 robots in *task2* are removed from the arena but the proportional demands are fixed. At time-step 40000, the demands are changed to 25%, 25%, and 50% respectively. The experiment is repeated for 25 independent runs.

Figure 8 represents the progression of the number of robots in each task over time. As it is demonstrated in the figure, the swarm reacts properly to the changes in the number of robots by switching a proper number of robots from *task1* and *task3* into *task2*. The system also quickly responds to the changes in the task-demands by switching two robots from *task2* to *task3*.

Figure 9 represents the frequency of switch-backs during the first 10000 time-steps of all the runs. The figure represents that about 0.47% of the robots have not a single switch-back during the whole evaluation-time and very few robots had more than 10 switch-backs representing specialization for the robots in the tasks they perform.

## Conclusion

This paper introduces a novel decentralized, self-organized and self-regulated division of labour in artificial swarms inspired by temporal polyethism in honey bees. The algorithm is based on local communication while the communications need to be possible only between the agents that perform the same task or neighbouring tasks. The logic behind the algorithm is simple and it is easy to implement while the interesting properties are maintained for the swarm. Experiments investigating the behaviour of the swarm in response to changes in the swarm members or task-demands represents that the algorithm provides a high adaptivity for the swarm. In addition, it is demonstrated that the agents are specialized in the tasks and unnecessary switchings between the tasks are limited. The sensitivity of the system to a pre-defined parameter of the algorithm (step-size) is also investigated indicating that there is a trade-off between the speed of approaching the solution and stability of the swarm. In the future the algorithm will be extended for more complicated requirements and will be used in real-robot scenarios.

Figure 7: A screenshot of the robot arena. Three different task-regions are located based on their distances from the light source.

Time	0	20000	35000
$th_{1:2}$	25	25	25
$th_{2:3}$	75	75	50
Swarm Size	16	8	8

Figure 8: Medians of the number of robots in each task in 25 runs. The system starts with 16 robots while the demands for the three tasks are 25%, 50%, and 25% respectively. At time-step 20000, all the robots in the second task are removed from the arena. In time-step 35000, the demands change to 25%, 25%, and 50% respectively. Tasks are represented with  $t1$ ,  $t2$ ,  $t3$ .

Figure 9: Frequency of number of switch-backs in the first 10000 time-steps for all the 16 agents and 25 runs.

## Abstract

The evolution of language has been the subject of much debate and speculation. It is difficult to study in a scientific manner and remains an open research question. This paper proposes an integrated computational framework for investigating possible scenarios of genetic and cultural evolution of language. Specifically, our framework aims to capture cultural evolution to allow for investigation phylogenetic dynamics of language, and at the same time to capture genetic evolution of phenotypic plasticity to allow for investigation of the role of the Baldwin effect in language evolution, while keeping the framework as simple as possible. In our evolutionary experiments and analysis, we discovered a coevolutionary scenario involving biological evolution of phenotypic plasticity, and a cyclic coevolutionary dynamic between genetic and cultural evolution, mediated by phenotypic plasticity.

## Introduction

Language distinguishes humans from other animals. Of course, other animals also engage in vocal communication. For example, Velvet monkeys can convey some simple information using alert calls (Sayfarth et al., 1980). However, such animals' vocal communication lacks the complex grammar and high expressiveness that characterizes human languages. Why do only humans have sophisticated language? This is one of the core questions on the path to understanding the human identity. This paper focuses on the evolution of the fundamental traits underlying communicative interaction in the context of biological evolution (genetic evolution of the language faculty), such as the rules or conventions for the effective communication necessary for collective behaviors. We assume that such traits can evolve under directional selection because the traits can be modified incrementally to increase the benefit from communicative interactions. We also assume such traits must be shared between individuals for communication to succeed. Accordingly, at least some of the selection will be positively frequency-dependent. This might obstruct evolution based on directional selection. We believe that this captures a fundamental and general problem in the evolution of communicative traits. For example, in the context of language

evolution it has been pointed out that mutations in grammar cannot be beneficial because the peers of an individual with a grammar mutation may not understand the mutant form (Pinker and Bloom, 1990; Glackin, 2010).

We believe that nature's solution to this challenging problem is found in the evolution of phenotypic plasticity. Phenotypic plasticity refers to the variability in the phenotype obtained from a given genotype resulting from development in different environments (West-Eberhard, 2003). In recent evolutionary biology, ontogenetic adaptation<sup>1</sup> based on phenotypic plasticity is recognized as one of the key factors that brings about adaptive evolution of novel traits (West-Eberhard, 2005; Gilbert and Epel, 2009). Wund provided a summary of eight hypotheses on how plasticity might influence evolution (including several pieces of empirical support), focusing mainly on adaptation to new environments (Wund, 2012). For example, the hypothesis that phenotypic plasticity promotes persistence in a new environment, and the hypothesis that a change in the environment can release cryptic genetic variation via phenotypic plasticity, in turn impacting the rate of evolutionary responses. Zollman and Smead (2010) analyzed simple models of language evolution based on Lewis's signaling game and the prisoner's dilemma game. They observed that the presence of plastic individuals alters the trajectory of evolution by directing the population away from a non-adaptive signaling and toward the optimal signaling. They termed this the "Baldwin optimizing effect". Suzuki and Arita also showed that such an adaptive shift can occur repeatedly, using a computational model of the coevolution of signal sending behavior and signal receiving behavior, that incorporated behavioral plasticity (Suzuki and Arita, 2008, 2012, 2013). These studies indicate that learning could be an important driving force for adaptive evolution in the context of communicative interactions.

This paper also looks at the relationships between two aspects of language evolution: biological evolution and cultural evolution. The relationship between genes and lan-

<sup>1</sup>Adaptive changes that occur during the lifetime of an organism (e.g., learning).

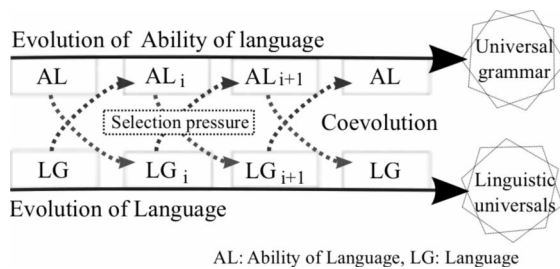

Figure 1: Coevolution between language and language ability. The upper arrow represents the evolution of language ability in general. The lower arrow represents the evolution of language itself. Language ability and language are represented by  $AL$  and  $LG$ , respectively.  $AL_i$  controls the selection pressures shaping  $LG_{i+1}$  and conversely  $LG_i$  controls the selection pressures shaping  $AL_{i+1}$ . Universal grammar (the theory proposing that the ability to learn linguistic grammar is hard-encoded into the brain) and Linguistic universals (general pattern that potentially exists in almost all of natural languages) may have emerged as an inevitable result of this coevolution.

guage is extremely complex and shrouded in controversy. Furthermore, rather than viewing language as a monolithic and independent entity, modern researchers typically break it down into its component mechanisms and analyze these independently (Fitch, 2011). Steels (2011) discussed various computational models of cultural evolution. He concluded that cultural evolution is a more powerful process than usually assumed, and that human language evolution's dependence on genetic evolution is relatively limited. Several researchers argue that cultural evolution has fundamentally limited influence on the genetic evolution of the language faculties. This contrasts with various results that indicate that genetic biases are essential to language evolution. For example, Chater et al. (2009) have shown using a computational model that there are strong restrictions on the conditions under which the Baldwin effect can embed arbitrary linguistic constraints, and that the effect only emerges when language provides a stable target for natural selection. These approaches should be seen as complementary. There is a need to integrate these efforts and explore the relevant gene-culture coevolutionary interactions (Mesoudi et al., 2011).

We suggest the insights from these studies of language evolution together can be brought together using the concept of coevolution between language and brain, as it lets us integrate biological and cultural evolution. The idea of coevolution was originally suggested by (Darwin, 1871), and others have taken up his lead (Deacon, 1997). As illustrated in Fig. 1, the main idea is as follows: On one hand, a language is continuously changed its users, which brings about the linguistic variation much like mutation brings about ge-

netic variation. Language variants that can easily be learned by their users can survive and thus spread in the population of languages. On the other hand, having innate linguistic abilities (e.g., universal grammar) that equip an individual to handle the existing language variants and language changes provide a fitness advantage. Thus, genes for an innate language faculty will spread in the biological population. So we have two intertwined adaptation processes: language adapts to the brain, and the brain adapts to language. We believe that this insight is crucial to a comprehensive understanding of language evolution.

In this paper, we employ the coevolutionary framework described above, and propose a bottom-up computational model for investigating possible scenarios of the genetic and cultural linguistic evolution. We aim to capture cultural evolution to investigate the phylogenetic dynamics of language evolution, while at the same time capturing genetic evolution of phenotypic plasticity. The latter allows us to investigate the role of the Baldwin effect (typically interpreted as a two-step evolution of the genetic acquisition of a learned trait without the Lamarckian mechanism (Peter Turney and Anderson, 1996)) in language evolution, all the while keeping the framework as simple as possible. In order to do this, we extend our previous works on language evolution (Suzuki and Arita, 2008, 2012; Azumagakito et al., 2011, 2012). The main idea is to express the linguistic space as a polar coordinate system, in which individuals and languages gradually move about by genetic evolution and cultural evolution, respectively, as follows: 1) the more an individual can communicate, and the higher the expressivity of its languages, the more offspring it can produce. This nudges the population toward the locations of fit individuals. 2) Languages move towards the center of their user base, and divide, merge or go extinct in accordance with the distribution of their users.

Recently, there is much research on the diversification processes of real human language (Pagel, 2009; Lupyán and Dale, 2010; Atkinson et al., 2008; Atkinson, 2011). Levinson and Gray (2012) reviewed various methods to investigate the diversification of languages, and observed that phylogenetic analysis techniques from evolutionary biology are useful tools for elucidating the diversification of language. Phylogenetic patterns of language evolution were uncovered using such analyses, but the causal mechanisms of diversification are still unclear. These previous investigations proceed within the observational and deductive realm. The framework proposed here provides the means for experimentation, and a method to generate phylogenetic trees that can help elucidate the causal mechanisms of language diversification (see Fig. 2).

2) Analyze the feature of estimated tree, for example word-order relation between language families.

Figure 2: Phylogenetic comparative analysis using the proposed framework. Simulation results based allow us to generate phylogenetic tree of language families. By comparing the experimentally generated trees with the trees inferred from real linguistic data sets (such as standard word-lists), we can elucidate how and what causal mechanisms may have brought about the features of the inferred trees, and verify the validity of our simulation model. In this paper, we generate a phylogenetic tree from an evolution experiment. A comparison of it with the inferred trees from the real linguistic data is our future work.

### Model

We propose an integrated computational framework for investigating possible scenarios of genetic and cultural evolution of language. This framework allows us not only to capture coevolutionary interactions between languages and agents, but also to track the phylogenetic evolutionary process of languages.

### The Linguistic Space

There are  $N$  agents in a population, and they can communicate with each other using their shared languages. Agents and languages exist in a two-dimensional linguistic space, represented as a polar coordinate system, as shown in Fig. 3. Each language ( $L$ ) is defined as a point in the space. The distance  $r_L$  from a language to the coordinate system's origin represents the language's expressiveness, which contributes to the expected fitness benefit of a successful communication in that language. The angle of the language  $\theta_L$  to the origin represents its structural character. Each agent ( $A$ ) is represented as a point and a field surrounding the point. This point represents the agent's innate language ability, determined by its genotypes  $r_A$  and  $\theta_A$ . The agent can use the corresponding language in the linguistic space without learning. The field represents its linguistic plasticity (i.e. the range of its linguistic learning ability), as a  $p_A \times p_A$  fan-shaped field determined by its genotype  $p_A$ . The agent can use any language that falls within its plasticity field for communication. This polar coordinate system captures the fact that, as expressivity increases, the space of possible linguistic structures grows, such that agents with more expressive languages will be harder to communicate successfully with, due to the limited size of the plasticity field.

Figure 3: The linguistic space.

### Linguistic Interactions

In each generation, all possible pairs of agents make an attempt to communicate. If the two agents of a pair share one or more languages, they can communicate successfully. The fitness of each agent depends on its number of successful communicative interactions, the expressiveness of the languages used in those interactions, and the cost of its linguistic plasticity. The fitness function is defined as:

$$Fitness = N_{ca}^{w_1} \cdot \left( \frac{\sum_{i=0}^{N_{ul}-1} r_{L_i}}{N_{ul}} \right)^{w_2} - (p_A^2)^{w_3}, \quad (1)$$

where  $w_i$  ( $i=1, 2$  and  $3$ ) are weights for the three components of the fitness function. The first component represents the benefit from successful communicative interactions, which is proportional to the number of agents with which the focal agent successfully communicated  $N_{ca}$ . The second component represents the benefit from the expressivity of the languages available to the agent.  $N_{ul}$  is the number of languages within the plasticity field of the focal agent, and  $r_{L_i}$  is the expressiveness of the  $i$ -th language among them. The second component is an approximation of the average expressiveness of the languages used for successful communications. We adopted an approximation in order to reduce the computational cost. The third component represents the cost of linguistic plasticity. It is proportional to the area of plasticity ( $p_A^2$ ), because the further a language is removed from an agent's innate language ability, the bigger the demands on the agent's plasticity, and thus plasticity for further and further removed languages comes with higher and higher costs for maintaining the requisite plasticity. Overall, this fitness definition reflects that agents who can communicate with many other using expressive languages acquired

with limited linguistic plasticity will have high fitness.

### Biological Evolution of Language Ability

After the communicative interactions of agents, biological evolution of language ability occurs as follows: 1) Parent agents for the next generation are selected using roulette wheel selection (i.e. the probability that an agent is picked as a parent is proportional to its fitness). 2) Each genotype of each offspring is mutated with probability  $P_m$ . Mutation adds a small random value of  $R(0.01)$  to the values of  $r_A$  and  $p_A$ , and of  $R(0.01/r_A)$  to  $\theta_A$ , where  $R(x)$  produces random numbers between  $-x$  and  $x$  with a triangular distribution. Note that the range of a random value for  $\theta_A$  is inversely proportional to  $r_A$  of the parent. This keeps displacement of the innate language ability of an agent and the change in plasticity independent from the location of the agent in linguistic space.

### Cultural Evolution of Language

Subsequently, the language population evolves according to four cultural processes: extinction, cultural change, division and fusion.

**Extinction** Any language that was not used by any agents in this generation do not appear in the next generation, and thus are removed from the linguistic space. This models the extinction of unused languages.

**Cultural change** The users of a language change its characteristics. We model a cultural change of language as a change in the location of the language within the linguistic space. Each agent creates, for every language it used, an attraction force (vector)  $F$  that drags the languages toward the agent's location, as shown in Fig. 4(a). The length  $F$  is  $f_{max}/N_{ul}$ , where  $f_{max}$  is the parameter that determines the maximum length of  $F$  and  $N_{ul}$  is the number of languages within the plasticity field of the agent. Each language moves to the location determined by the resultant vector of all the forces exerted on it. Fig. 4(a) shows an example of cultural change of language.

**Division** A language is divided into two languages if the forces of cultural change strongly pull it in opposing directions. Fig. 4(b) shows an example process of a language division. To determine the direction of a division of a language, we adopt "Principal Component Analysis" (PCA) (Pearson, 1901). Because the first component axis of PCA on the forces working on a language corresponds to the direction of the forces' maximum variance, we use the second component axis ( $L$ ) to divide the forces into two groups. We calculate the resultant force for each group. A division process occurs when the length of either or both resultant forces is larger than the threshold parameter  $Div_f$ . These resultant forces are then used to determine the locations of the two languages resulting from the division.

Figure 4: Panel (a) shows an example of a cultural evolution step of a language. Note that agents (i), (ii) and (iii) can each use another language (not shown) besides the focal one. Therefore, their pulling forces are only half that of agent (iv). Panel (b) shows an example of a language division process.

**Fusion** When the distance between two languages is close enough, these languages are united into one language. This process occurs when two languages' difference in distance to origin and angle to origin are smaller than the thresholds  $\beta$  and  $\gamma$  respectively.

Through the above processes, the agent population and the language population coevolve.

### Simulation Results

We conducted evolutionary experiments for 30000 generations and visualized the results in the linguistic space. The following parameters were used:  $N=2000$ ,  $w_1=1$ ,  $w_2=1$ ,  $w_3=30$ ,  $P_m=0.01$ ,  $Div_f=0.00003$ ,  $\beta, \gamma=0.001$  and  $f_{max}=0.00003$ . The initial values of  $r_A$  and  $r_L$  were picked at random from  $[0, 0.001]$ .  $\theta_A$  and  $\theta_L$  were picked at random from  $[0, 2\pi]$ .

Fig. 5 shows an example run of this experiment. We observed a typical evolution scenario, which we summarize in Fig. 6. From the initial population, both agents and languages are aggregated around the origin of the linguistic space. At this stage agents communicated successfully with each other using just a few languages at around the origin, because their innate linguistic abilities were quite similar. From there onward, we observed that (0) the number of languages rapidly increased until the 250th generation, reached to around 40 languages. This could be interpreted as a "Linguistic burst". This is thought to be due to the high concentration of agents around the origin easily leads to opposing cultural pull and hence frequent language division.

After the 250th generation, we observed cyclic coevolution processes of languages and agents. Let us look at the evolution process from the 7500th to the 13500th generation (i-iii) as example. Around 7500th generation, we see agents with smaller plasticity fields clustered densely together. In

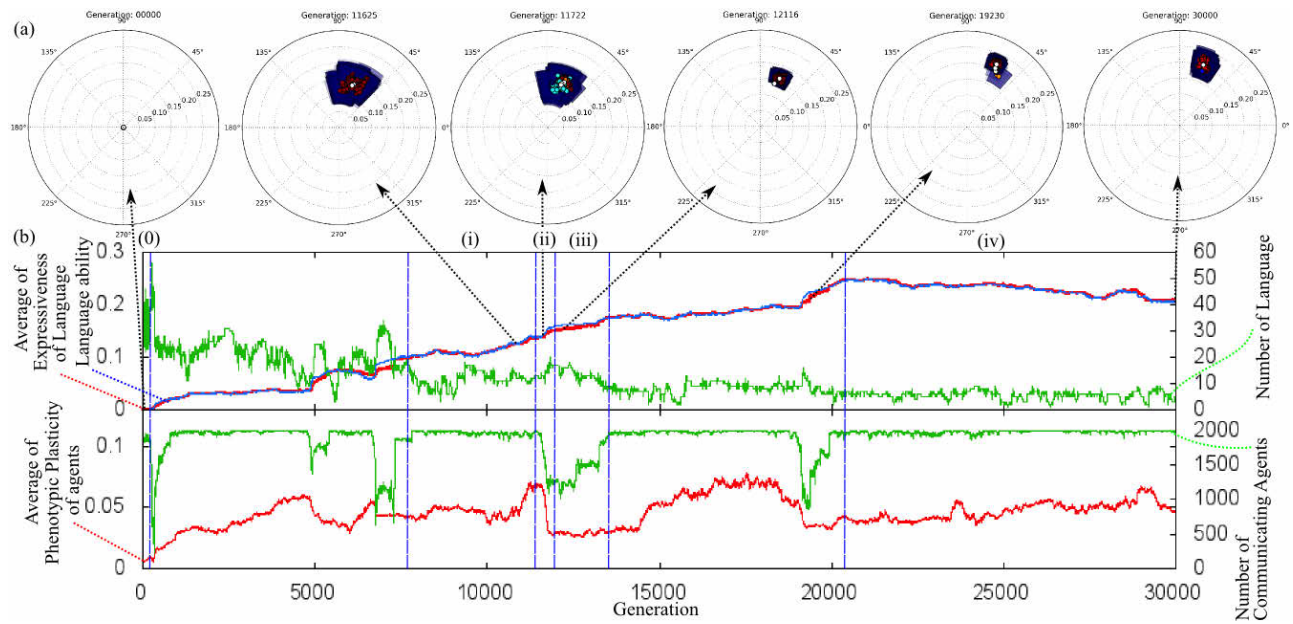

Figure 5: An example evolution process. (a) Several snapshots of coordinate distributions of languages and agents. Each agent is shown as a colored circle, with its color representing its fitness, and a fan-shaped field representing its linguistic plasticity. Languages are shown as white circles. (b) Evolution plots. The x-axis shows the generation number.

this situation, there is only weak selection pressure on innate language ability, because agents can already communicate successfully. This lack of selection leads innate language abilities to scattered by neutral evolution. This in turn leads to a gradual increase in phenotypic plasticity until around the 11500th generation (i), because additional plasticity became necessary for the agents to keep their communication successful. Then, around the 11500th generation, some agents with more expressive innate language ability and lower phenotypic plasticity appeared (ii), and occupied the population quickly. Instead of communicating with many agents in less expressive languages while incurring high plasticity costs, these agents communicate with a limited number of neighbors using more expressive languages while incurring only a small plasticity cost, which results in a net relative fitness gain. Thus, the average expressiveness of the innate language ability became larger than that of the existing languages, and the number of successful communications decreased drastically. Note that the number of languages increased because languages were dragged by two groups: the group of agents with more expressive ability of language and the group of the agents with less expressive ability of language.

After that, from the 11800th generation until the 14700th generation, the language population evolved toward the languages used by these adaptive agents, via a process of cultural evolution arising from the increased use of the more

Figure 6: Typical scenario of evolution process.

expressive languages (iii), increasing the number of successful communications among agents again. Languages now

Figure 7: The generated phylogenetic network of languages (from the 250th to the 20000th generations). Each black node represents a language, and each link between the left node and the right node represents the genealogical connection between the ancestral language and its offspring language. There are 64389 nodes and 91976 links in this tree. The language division occurred 45838 times and fusion of language occurred 23802 times. The death of language occurred 22036 times.

distant from the agents' (shifted) innate language abilities go extinct, leading to a gradual decrease in the number of languages. As a result, language expressivity caught up with the expressivity of innate language ability, i.e. both the agent population and language population moved outward from the origin, and the overall system state was back at the initial state of a cycle. As this cyclic coevolution processes repeated, the expressiveness of languages and agents' innate language ability increased, while overall the number of languages decreased. This could be interpreted as the emergence of major dominant languages (Abrams and Strogatz, 2003). The cyclic mechanism can be summarized as follows: (i) The phenotypic plasticity of the agents increases gradually due to the selection for the robustness of successful communications against the increased genetic variation of the innate language ability by a genetic drift (caused by the previous step). (ii) Some agents with the more expressive innate language ability and the smaller plasticity occupy the population quickly because they can communicate using more expressive languages than other agents with the larger plasticity. (iii) The expressiveness of languages increases and the diversity of languages decreases because the languages are dragged by the agents with more expressive language ability. This brings back to the process to the beginning, because the small fitness differences due to the very few number of different languages creates the variation of the innate language ability of agents.

However, (iv) the evolution process eventually halts once the expressiveness of languages reached the high value of 0.2 after the 20000th generation. This is thought to be due to the fact that it became increasingly difficult for agents with relatively high expressiveness to maintain enough plasticity for successful communications, as the increasing cost cancels out the benefit of their expressivity.

In addition to the above analysis, we show the phyloge-

netic network of languages for our basic simulation experiment (Fig. 7). We found that a process of diversification and unification of languages emerged through repetition of the interaction processes between genetic and cultural evolution that we described in the previous section. In previous studies of language change, the phylogenetic relations of language families is generally represented as a tree (Gray and Atkinson, 2003). Fusion of languages cannot be captured using a tree representation. However the generated network showed that language fusion occurred frequently. This shows the important role the cultural processes of fusion plays in the evolution of language within our model.

Finally, we conducted experiments to study the effects of the model's parameters on the evolution process. First, to investigate the effect of learning cost, we conducted experiments with various settings of the weight on the learning cost,  $w_3$ . We found that the duration until the population reached the coevolution phase increased as  $w_3$  increased. A higher cost of learning puts the population under stronger selection pressure for low plasticity. Because individuals with the low plasticity were less robust against mutations and often failed to leave offspring, evolution speed dropped. Also, the speed of the increase in the expressiveness of languages was inversely proportional to  $w_3$ , due to the increased duration until the start of the coevolutionary phase. For example, in the case of no cost ( $w_3 = 0$ ), the duration was quite short: the coevolutionary phase started after about one hundred generations. In the case of a huge learning cost ( $w_3 = 100000$ ), the evolution of language and population stagnated around the origin, because individuals could not increase their plasticity at all. It also should be noted that higher values of  $w_3$  lead to shorter cycle period. This is thought to be due to the fact that the rapid decrease in phenotypic plasticity (ii) tends to occur more often as the cost

of plasticity increases.

We also investigated the effects of  $f_{max}$  which determines the strength of the attraction force that pulls a language toward its users. Because this parameter is used in the processes of cultural change and division of languages, we assumed the condition in which the threshold for the division  $Div_f$  was proportional to  $f_{max}$  ( $Div_f = f_{max} * 300$ ) in order to mainly focus on the effects of change in  $f_{max}$  on the process of cultural change. Experiments with different settings of  $f_{max}$  (from  $1.0 * 10^{-7}$  to  $1.0 * 10^{-4}$ ) showed that the chances of all languages dying off during the early generations increase with increasing  $f_{max}$ . This is because at large  $f_{max}$ , when there are many individuals pulling on a language, the resultant of the attraction forces tend to be so large that it displaces the language outside the plasticity ranges of the agent population. However, once the initial increase in the number of languages (0) has started successfully, we see a more rapid increase in the expressiveness of languages in the cyclic processes, because the larger pulling force facilitates rapid adaptation of in the language population. Especially in trials at high  $f_{max}$  ( $1.0 * 10^{-5}$ ), successful evolution was only observed when by chance the initial population had high plasticity. At extremely high  $f_{max}$  ( $1.0 * 10^{-4}$ ), all trials failed in about 10 generations.

### Discussion

Cultural linguistic change is often assumed to be much faster than biological change. Chater et al. (2009) showed, using a computational model, that genetic natural selection may not keep pace with a language change. Conversely, Számadó and Szathmáry (2012) argued that there are many ways for organisms to adapt to quickly changing targets, and showed numerous examples of rapid evolutionary change. For example, the rate of biological adaptation depends on the population size and genetic variation. This means that there is a possibility that biological adaptation too can be quick. Also, the phenotypic plasticity of a genotype effectively could facilitate adaptation, via the Baldwin effect. On the other hand, they also pointed out the possibility that the rate of language change could slow down. Historically the rate could have been much slower than it is now, due to smaller population sizes, slower rates of technological innovations, more limited contexts of language use, and much smaller vocabulary. Furthermore, the rate of linguistic change depends on frequency of use: words and rules used more frequently evolve far slower.

The experimental results obtained using our framework of genetic and cultural evolution of language demonstrates that the rate of language evolution could change through cyclic coevolutionary processes. This partly support Számadó et al.'s claims, especially with regards to the way phenotypic plasticity promotes adaptation. In addition to Számadó et al.'s claims, we obtained the following insights from our simulation: 1) Diversity across language groups increases

fitness variance, which accelerates the rate of biological evolution. 2) The rate of cultural evolution tends to be restricted by the plasticity of individuals, as languages cannot survive outside of the linguistic plasticity range of individuals. 3) The rate of cultural change can be slow, especially when individuals reduce their learning cost as they cluster around existing languages with sufficient expressiveness for communication. In contrast to situations with no linguistic conventions among speakers, this tends to lead language evolution to stagnate. We think that the rate of cultural change may be faster when there are no linguistic conventions among speakers, and slower when some shared conventions exist among them.

### Conclusion

This paper proposed an integrated framework for investigating genetic and cultural evolution of language. On basis of this framework, we constructed an agent-based model capturing both cultural evolution of languages and biological evolution of linguistic faculties, expressed on a two-dimensional linguistic space. Our evolutionary experiments showed that, after an initial rapid increase in the number of languages, a cyclic coevolution process occurs in which biological evolution and cultural evolution proceed in alternation. Here we observed genetic assimilation of language into innate linguistic ability. Eventually, the population reached languages with high expressiveness. Our model can be regarded as an "emergent computational thought experiments" (Bedau, 1999), or "opaque thought experiments" in which the consequences follow from the premises in such a non-obvious manner that the consequences can only understood through systematic enquiry (Di Paolo et al., 2000). We believe our model can also be extended to function as a realistic simulacra type of simulation model. For this purpose, we should further investigate what parameter settings correspond best to reality, especially in regard to the relative speeds of cultural and biological evolution.

### Abstract

Ecosystems are subjected to a range of perturbations that have the potential to induce relatively sharp transitions in states. These can be referred to as regime shifts or critical transitions. They may be driven by perturbations that vary over a wide range of spatial and temporal scales, from responses to deforestation within a small field to responses to the gradual increase of carbon dioxide in the Earth's atmosphere. Here we investigate potential early warning signals that may presage regime shifts in model ecosystems. We hypothesise and model a relationship between biodiversity and community structure that influences ecosystem structure. We argue that Artificial Life methodologies have potential to make substantial contributions to efforts searching to predict large changes in ecosystems and other elements in the Earth system, as there is a recognised limitation in empirical data and ability to conduct experiments in the real-world. Consequently simulation and exploration of the low-level mechanisms that give rise to regime shifts in artificial in-silico ecosystems represents a useful line of enquiry.

### Introduction

The relationship between complexity and stability is a well established topic in ecology (McCann 2000). Much of this discourse stems from May's seminal paper that found an inverse relationship between diversity and stability in simple model ecosystems (May 1973). As the number of linear connections between species increased, the probability that the ecosystem would be stable decreased.

Here we explore to what extent the complexity of artificial systems, and by extension real-world ecosystems, can be used to provide early warning signals of impending large changes in their states - sometimes referred to as regime shifts. That is, we do not explore the (causal) relationships between complexity and stability, rather we seek to leverage the maximum amount of information from very often complex systems in order to give an indication of how stable the system is to perturbations and how close they are to collapse.

Dynamical systems theory has been applied to a range of real-world systems in order to determine to what extent they exhibit bistability and the potential to undertake catastrophic fold bifurcations, and thus rapid changes from one attractor

to another (Scheffer et al. 2001). One example of this phenomenon is the eutrophication of a lake. When a lake is subject to nutrient loading, changes may occur from a state of clear water with rich submerged vegetation to a turbid one without submerged vegetation and loss of animal biodiversity. At early stages, water clarity seems little affected by increased nutrient concentrations until a critical threshold is reached. Once this threshold is passed, the lake abruptly shifts to a turbid stable state.

Given the range of perturbations facing ecosystems and an increasing awareness of their contribution to human well being in the terms of the services they provide, a great deal of research effort is being devoted to formulate robust early warning signals (Scheffer et al. 2012; Lenton et al. 2012). Leading indicators of impending regime shifts have been identified that operate regardless of the underlying processes driving the change (Scheffer et al. 2009; Carpenter and Brock 2006; Guttal and Jayaprakash 2008). Some studies however, have identified the potential for false positives or even an absence of signals (Hastings and Wysham 2010), and studies of the drivers of regime shift reveal other signals in community composition (Scheffer and Nes 2007). The sooner a warning can be detected, the more time is available to act on it. The challenge is to find signals that warn at the earliest opportunity but do not provide false alarms.

Our ability to conduct experiments on real-world ecosystems is often very limited. For example, studies of regime shifts in the Lake Erhai, Yunnan Province, in China involved gathering then analysing sediment cores along with the integration of large amounts of socio-economic data (Wang et al. 2012). At this scale, it is effectively impossible to manipulate ecosystem variables let alone ensure control systems are available to compare experimental results. One way to increase our understanding in this area is to perform simulation experiments on artificial ecosystems. Such simulations can be understood as conceptual models that produce data appropriate for statistical analysis and so allow the development of proof of concepts and initial hypothesis testing.

Our starting assumption is that regime shifts in real-world ecosystems are often a consequence of changes in the abun-

dance of keystone species. A keystone species is a species that has large effects on its environment and consequently plays a key role in the maintenance of the structure and integrity of its ecosystem. The loss of a keystone species will be expected to produce changes in a large number of other species such that the entire ecosystem may transition to a new state: a regime shift.

If we seek to undertake interventions and so avoid future regime shifts, waiting to observe changes in keystone species may be too late as the transition is already in progress. We propose instead monitoring properties of ecosystems that includes measures of complexity and structure. The novelty of our method is in using as detectors the species most vulnerable to extinction, which we term the ‘ecosystem canaries’, whose response to the perturbation precedes the approach to a critical tipping point. Provided they are correctly identified as sensitive to the driver of environmental change, they are not prone to false alarms. Provided they are not keystone species, their signal precedes those of the leading indicators for imminent critical transition.

### Nestedness and biodiversity analyses

We hypothesise that biodiversity has a relationship with ecosystem structure that depends on important properties of the dynamical system. In this section we define ways to measure both the biodiversity and the structure of a community. Then we correlate these measurements over time to investigate the relationship between these quantities under different stress regimes.

#### Hill’s biodiversity analyses

Species diversity has two main components: abundance of each species and species richness (Magurran and Magurran 1988). Hill’s biodiversity indices incorporate these two components in a single value and are easy to interpret ecologically. The index value increases when either the number of species or the evenness of the community increases. In this study, we use Hill’s biodiversity index  $N_2$ ,

$$N_2 = \frac{1}{\sum_{i=1}^S p_i^2}, \quad (1)$$

which is the inverse of the commonly used Simpson’s diversity index  $\sum_{i=1}^S p_i^2$  (Simpson 1949). Here  $S$  is the number of species and  $p_i$  is the proportion of the  $i$ th species in the community (Hill 1973).

Simpson’s diversity index indicates the probability of finding an already observed individual by randomly choosing it from the community (Simpson 1949). Hence, the larger the value of Simpson index, the less diverse the community will be. Contrastingly, the higher the value of Hill’s biodiversity index  $N_2$ , the more diverse the community will be.

### Nestedness analyses

If we assume that a community is an assemblage of meta-communities, where each meta-community contains a subset of the species found in richer meta-communities, then we can ask: how much information about the structure of the community can we obtain when we observe a single species? The answer is potentially a surprising amount, if we also understand how nested the community is.

The concept of nestedness was first introduced as an explanation of insular faunal structure where species abundances decrease with distance of islands from a continent and species in distant islands are a subset of species in proximate ones (Patterson and Atmar 1986). Latterly, the concept has been applied extensively to terrestrial communities (Cutler 1991; Fischer and Lindenmayer 2005).

Nestedness is a characteristic of the interconnectedness of species in a community (Ulrich et al. 2008). If a community is completely nested, the community structure and composition may be predicted entirely from the presence of the least abundant species; if it is completely un-nested, its composition is unpredictable, as in the case of communities with a high flux of species.

In general, nestedness studies focus on the analysis of spatial data (Rodríguez-Gironés and Santamaría 2006), or spatial analyses replicated through time (Timi and Poulin 2008; Heino et al. 2009). However, nested temporal assemblages can occur when most species respond similarly to inter-annual variation in conditions. In contrast, assemblages might be non-nested when different sets of species occur in different years (Elmendorf and Harrison 2009). Here we develop a novel approach in which measures of nestedness are computed for communities that change only temporally and not spatially (see Fig. 1).

Figure 1: Nestedness in the structure of insular communities shows decreasing species abundance  $S$  with distance from mainland. Island  $S(I_n)$  contains a subset of the species found in previous islands so  $S(I_n) \in S(I_{n-1}) \in \dots \in S$ . Analogously, a given community  $S(t_n)$  at  $t = t_n$  can be seen as a subset of the community  $S(t_0)$  at  $t = 0$ , such that  $S(t_n) \in S(t_{n-1}) \in \dots \in S(t_0)$ .

One way to measure the nestedness of a community is via its incidence temperature (Patterson and Atmar 1986). This temperature ranges from 0 (completely nested) to 100 (completely un-nested), and provides a measure of the species richness across non-chronological times with respect to their incidence. The use of the term “temperature” can be understood from physical analogy: as the temperature of a collection of molecules increases then this additional energy will typically lead the molecules to occupy a larger volume. Knowing the position of a single molecule in a low temperature systems provides more information about the location of all the other molecules than higher temperature systems.

Originally, the nestedness temperature was presented as a measure of the degree of uncertainty in species extinction order and was linked in perfect analogy with the entropy of a system (Atmar and Patterson 1993). Recently, it has been argued that the nestedness temperature does not increase with extinction disorder (Almeida-Neto and Ulrich 2011) and therefore it cannot be explained as the inverse of the entropy (Almeida-Neto et al. 2007). However, nestedness temperature does give a measure of the community structure dependent on the community distribution. In this sense, nestedness temperature may be measured in non-dimensional units of entropy where a completely structured community would have the lowest entropy while completely disordered communities would have maximum entropy values.

## Hypothesis

According to Montoya et al. (2006) the interaction between species in an ecosystem may be so complex as to be impossible to understand. Here we argue that, although interactions between species in a community are very complex, the underlying mechanism of their dynamics are reflected in the structure and biodiversity of the system. If we think of an ecosystem as a complex network where each species may (or may not) be associated to other species, the structure of this network will certainly affect the function of the system (Strogatz 2001). Inter-species connections may be trophic in the sense of who eats whom, or competitive in the sense of who competes for whom over a food or resource. They may also emerge from ecosystems engineering effects (Jones et al. 1994) where one species alters the environment for another. As we are motivated to produce a general hypothesis in which if the structure of a community at a given time is affected by its biodiversity, we deliberately do not prescribe on the type of interactions among species. Instead, we propose that a correlation between nestedness temperature and Hills Biodiversity index may exist.

We assume that a community is composed of different types of species among which we can find keystone species, interacting species and “canary species”. The keystone species are those with a large effect on the system, the interacting species will also be linked to other species in the

community, while the presence or absence of canary species will have little impact. Canary species are also the most vulnerable to extinction. Consequently they will be rare in the community and will have little or no interaction with other species (see Fig. 2).

Figure 2: A community of species represented by their interactions with each other. Red dots represent keystone species, which are the species with the most links in the community. Blue and black dots are interacting species with fewer links to other species. Green dots are canary species, which are relatively isolated from the community and have very few links with other species. The lines between dots correspond to the links between species. Modified from Krebs (2012).

Figure 3: Increase of phosphorus influx into a lake drives the system from an oligotrophic state (clear water) towards a regime shift characterised by a eutrophic state (turbid water) passing through three stages (a) – (c). We propose that a negative correlation of nestedness temperature to biodiversity arises in stage (b) because rising stress on the community (phosphorus influx in this case) causes species accumulation rather than turnover with the loss of canaries and consolidation of strong competitors. During and after the regime shift (stage (c)), both the biodiversity and the nestedness temperature decrease and the system becomes a compact, nested community with very few species left. This produces a positive correlation.

For a potentially broad range of ecosystems that are characterised as having well-mixed or homogeneous environmental variables, we propose three key stages towards a regime shift (see Fig. 3).

- (a) Long before the regime shift: Temperature and biodiversity both fluctuate without obvious trend in biodiversity and temperature. However there is a weakly positive correlation (i.e., more biodiversity correlates with more disorder). This represents a healthy community that adds and loses canary species more or less at random.
- (b) Prior to the regime shift up to its cusp: Temperature and biodiversity fluctuate without obvious trends in either, but now with a strongly negative correlation (i.e., more biodiversity correlates with less disorder). Upward fluctuations of biodiversity add competitively dominant (keystone) and fast-fugitive (weedy) species at the expense of canaries, thereby also raising order. In effect, the out-of-phase fluctuations of biodiversity and temperature ratchet out the canaries and replace them with more strongly connected species, reflecting a tightening of the community in response to stress.
- (c) During and after the regime shift: Temperature falls dramatically with biodiversity in a strongly positive correlation, as keystone species are lost, leaving only the few most abundant and robust (weedy) species that have always been present.

These hypotheses and assumptions are consistent with empirical results obtained from Lake Erhai, Yunnan Province of China. A dataset for changes in a diatom community over time was obtained from a 63-cm sediment core in Lake Erhai, representing about 500 years of sedimentation prior to a critical transition in 2001, and 8 years post-transition. We developed a temporal analysis of the diatom community to obtain information about the community composition and structure before and after a critical transition that took place in 2001, according to results found by (Wang et al. 2012).

Before the critical transition, the community shows relatively high temperature (low levels of nestedness), though decreasing gradually towards the tipping point. During and after the critical transition, temperature decreases drastically. We correlated nestedness temperature with community biodiversity, finding that the sign of the correlation switched from positive to negative at about 50 years prior to the tipping point, and then back to positive immediately after the tipping point. We interpret these changes as a potential signal of ecosystem stress, which leads to the community tightening up as it loses first the canary species and finally the keystone species as it goes over the critical transition.

These empirical results provide a benchmark for the generation and analysis of the artificial ecosystems presented below. With limited capacity for further progress through analyses of empirical datasets, because of the financial and time costs involved in obtaining them, we perform numerical simulations of communities similar to the ones found empirically, and we test our assumptions on them. Such

simulations can be understood as an initial evaluation of our hypothesis. A next step would be the development of more detailed agent based models that would explicitly capture the important processes that we identified in (a), (b) and (c) above.

## Methods

### Simulation experiments

We generated artificial ecosystem matrices, that simulate community distributions of species under the influence of different types of stressors. The objectives of these simulations are: (1) to test for variations in the nestedness temperature in response to stressors, and (2) to identify relationships between nestedness and biodiversity through time. We anticipate that the results of these numerical models may point towards a robust early warning signal for regime shifts in community composition.

### Calculating nestedness

Nestedness temperature measures how much the incidence matrix departs from perfect nestedness. To calculate this metric, the list of species present in a series of times is summarised in an incidence matrix of presence-absence. The rows and columns of the incidence matrix are reordered so that nestedness is maximised, using the algorithm proposed by Rodríguez-Gironés and Santamaría (2006). The matrix is re-arranged to show species presences on the top left corner and the absences away from the top left corner. This creates a matrix where the columns rank species rarity (increasing from left to right) and the rows rank species richness (increasing bottom to top). Then an isocline of perfect nestedness is calculated to show the expected distribution of presences if the matrix were perfectly nested.

Absences to the top and left of the isocline are defined as unexpected, and so are presences below and to the right (see Fig. 4). The matrix nestedness temperature is calculated as the sum of squared deviations from the isocline of unexpected presences and absences divided by the maximum value possible for the matrix, multiplied by 100. Thus, the temperature is a non-dimensional index measuring how much the matrix departs from the perfectly nested state (Rodríguez-Gironés and Santamaría 2006; Almeida-Neto et al. 2007).

### Generating power-law population distributions

Many populations follow power-law frequency distributions with respect to their abundance across time (Mitzmacher 2004; Allen et al. 2001). Accordingly, we generated power-law frequency distributions of theoretical communities which we used as the basis of numerical experiments. We generated a matrix with 150 rows and 150 columns, where the  $M(i, j)$  represents the species in column  $j$  at time  $i$ . Each row is an independently generated power-law community distribution of 150 species.

Figure 4: Incidence matrix of  $m$  species identities (ranked from most to least often present), in  $n$  samples (ranked from most to least species rich, bottom to top). The isocline curve corresponds to the theoretically perfect nested structure of the system. All the red squares are presences and white squares denote absences. Temperature is calculated from the sum of all squared deviations of unexpected presences/absences  $u_{ij} = (d_{ij}/D_{ij})^2$ . Modified from Oksanen 2012.

Once a core matrix was generated, we applied a number of forcing functions to it. By doing this we introduced what would be analogous to stressors of change in the environment (e.g. changes in nutrients, salinity, pH). The proposed functions had an immediate effect in the change of nestedness temperature across the nested blocks over the temporal scale. Equally, these changes in the community structure, affected Hill's biodiversity index. The main objective of these numerical simulations was to obtain correlations between these quantities to compare to the empirical data on diatoms from Lake Erhai.

### Core matrix analysis

Using the method proposed in the previous section, we generated 100 matrices with power law distributions. Each core matrix was transformed into a presence-absence matrix from which we found an average nestedness temperature of  $T \approx 87.57$ . Figure 5 shows the nestedness temperature for a matrix with these characteristics. The high temperature of the community matrix does not show any type of structure. However, as we will see in the next section, when the system was subjected to external perturbations, the community acquired structure and the nestedness temperature decreased.

### Forcing functions

We have limited knowledge of the type of stressors acting on a real ecosystem. Consequently, we formulated a series of forcing functions that reduce the number of species in the community proportional to the value of parameter,  $z$ . The different forcing functions affect the abundance of species in

Figure 5: An example of a high incidence temperature system that shows little structure. A dataset with 150 species following a power law distribution for 150 times depicts an incidence temperature of 87.5. The continuous black line represents the isocline for a perfectly nested structure. The empty squares above the isocline denote surprising absences, while the red squares below the isocline denote surprising presences.

different ways. For example one forcing function will preferentially remove species with high abundance, another will reduce species with low abundance. We are motivated to do this as we seek to understand how the correlation between nestedness temperature and biodiversity changes under different perturbations and stressors.

**Max** Eliminates the species with the highest number of individuals in each row:  $f(z) = M_{i,K} - \frac{\max(M_{i,K})}{2} - z$ . These species are located in the peak of the distribution, and must exceed  $\frac{\max(M_{i,K})}{2}$  because the number of species with such high abundances is very small.

**Min** Eliminates the species with the lowest number of individuals in each row:  $f(z) = M_{i,K} - \min(M_{i,K}) + z$ . These species are located in the tail of the distribution and comprise a large percentage of the community.

**Middle** Eliminates the most abundant and the least abundant species, retaining those in the middle of the distribution:  $f(z) = \min(M_{i,k}) + z < M < \frac{\max(M_{i,K})}{2} - z$ .

**Outflux** Decreases the number of individuals of each cell in the matrix by a percentage  $z$  given by a fixed parameter  $f(z) = M_{ij} - z$ .

**In-Out** This function simulates the influx and outflow of individuals  $f(z) = M_{ij} - z + i$ . The population in each cell increases with time (row number  $i$ ) and decreases with the size of  $z$ .

Here we have assumed that  $M_{i,K}$  corresponds to the  $i$ th row for all the columns of the matrix  $M$ ,  $M_{ij}$  correspond

Figure 6: Changes in nestedness temperature of an artificial community of 150 species, over 150 time steps in response to increasing intensity ( $z$ ) of each of six stressors. The stressors that eliminate the rare species first (e.g., **Min-Outflux**) tend to reduce nestedness temperature most rapidly, reflecting an increased ordering and predictability in species composition. Function **In-Out** simulates a continuous flux of species through the community, which raises nestedness temperature from zero, reflecting the reduced predictability of composition induced by the turnover of species.

to the cell  $(i, j)$  of the matrix and  $z$  is a scalar parameter of fixed value. These functions are not an exhaustive selection; they give general indications of what responses stressors might induce in an originally well-mixed community.

In order to calculate how nestedness temperature changed over time in response to the different forcing functions, each matrix was divided in 135 consecutive nested subsets, where each subset had 15 rows (i.e. rows 1 to 15, then rows 2-16, 3-17, and so on). The nestedness temperature was then obtained for each subset.

### Results

The nestedness temperature varied with respect to the forcing function and the size of the forcing parameter  $z$  (see Fig. 6). In the cases of functions **Max**, **Min**, **Middle** and **Outflux**, the temperature decreased as the intensity of the forcing function increased (as  $z$  increases), with differently decreasing curves depending on the forcing function. This is expected since as the number of species decreases losing the canary species, the community becomes more nested. In the case of function **In-Out**, we observed that the nestedness temperature increased from 0 to 34.57. The reason for this is that the competing in- and out- fluxes balance each other as the parameter  $z$  increases. When  $z = 0$  the population in each row increases with the row number, e.g. each species in row  $i$  will increase in  $i\%$  adding more individuals to the community. As  $z$  increases, individuals leave the row community  $i$ , balancing out the fluxes into and out of the community. Consequently, when  $z \geq 100$ , the population only decreases until it eventually vanishes.

As a preliminary analysis, we choose three matrices from the whole set displayed in Fig. 6 and investigate the possi-

ble correlations between the community structure and biodiversity. We analysed relatively nested communities with nestedness temperature of about 25 units for three forcing functions in order to determine how a drop/increase in temperature and Hill's biodiversity changes the correlation between these two quantities. The results for these analyses are summarised in Table 1.

We chose functions **Min** and **Middle** since they best account for a linear loss of canary species, while **In-Out** shows drastic changes in nestedness temperature. Our analysis shows that a linear increase or decrease in nestedness temperature maintains the sign of the correlation between temperature and biodiversity. This implies that changes in community structure will maintain the same type of dynamics on the biodiversity. Conversely, we found that a sharp decrease or increase in nestedness temperature changes the correlation sign. The best example for this change of sign in the correlation is given by function **In-Out** displayed in Fig. 7.

Function	Rows	T	H	$r$	$P$
Min	20 – 75	+	n.t.	+0.228	0.0940
	80 – 110	–	n.t.	+0.287	0.1229
Middle	2 – 82	n.t.	n.t.	+0.164	0.1444
	82 – 112	–	n.t.	+0.320	0.0897
In-Out	1 – 7	n.t.	+	–0.620	0.0657
	8 – 20	++	++	+0.856	0.00001
	21 – 32	--	--	+0.428	0.0016
	33 – 60	n.t.	–	+0.665	0.0425

Table 1: Trends in nestedness temperature (T) and Hill's biodiversity (H) and their correlation coefficient ( $r$  and significance  $P$ ). Trends are + or ++ for weakly or strongly positive, – or -- for weakly or strongly negative, n.t. for no trend. Correlations between nestedness temperature and Hill's biodiversity index show that linear changes maintain the sign of the correlation, while drastic changes result in a correlation shift.

A sharp change of temperature and Hill's diversity index results in a change of correlation sign from negative (while the biodiversity starts increasing the nestedness remains more or less constant due to the species flow into and out of the system) to positive (a sharp increase in biodiversity results in a higher temperature due to the large influx of individuals into the community), then a sharp drop in the temperature and Hill's diversity index results in a positive correlation (as biodiversity decreases sharply the temperature decreases as well as only few structured species remain). Notice that after this decrease in temperature and biodiversity, the correlation remains positive. This is due to the continued decrease of biodiversity and temperature after the shift. Notice also that, when the drop of the temperature is abrupt, the correlation is stronger.

Figure 7: Nestedness temperature and running average of Hill's diversity index  $N_2$  for the numerically generated matrix **In-Out** with a stress intensity of  $z = 30$ . Both, the temperature and the Hill's index increases and decreases very drastically between row 8 and row 30. The arrows between vertical dotted lines show the regions analysed to obtain the correlation between these two non-smoothed quantities. These correlations are summarised in Table 1.

## Discussion

Our study of the biodiversity and nestedness of an artificial ecosystem aims to identify sensitive detectors of changes in environmental processes that drive regime shifts. Our hypothesis assumes that “canary species” (those most susceptible to extinction) function as detectors of drivers of change, preceding the approach to a critical tipping point.

We generated artificial populations with power law distributions and subjected them to a number of drivers of change. We correlated nestedness with biodiversity and established which conditions of external stress produced which correlations. We found that large changes in biodiversity and nestedness can lead to significant changes in the sign and magnitude of the correlation of the two measures. Such a change is qualitatively similar to that observed in a real-world lake ecosystem. We hypothesise that the change in correlations in the lake system are produced by the loss of ecosystem canary species in response to external perturbations. As these vulnerable species are lost the community ‘tightens’. Increasing the intensity of perturbation would lead to further changes such that keystone species were affected. This would not only change the correlation between biodiversity and nestedness, but also lead to an imminent collapse in the systems as major ecosystem level properties and structure would rest.

Our analysis presented here was performed for a small number of systems. In order to further explore the utility of an early warning signal of an impending regime shift that is generated by the correlation of biodiversity and nestedness we propose the development of a series of agent based models that would build on this initial work. These models would allow the inclusion of traits such as growth rate

and competitive ability. In doing so we would be able to explore the interactions between competitively dominant but slow growing keystone species, fast growing but competitively weak species and canary species that are both poor competitors and slow growing. If our initial assumptions are correct, then what would emerge in response to progressive perturbations on the population would be a robust indicator of a regime shift.

## Abstract

In studies of social behaviour it is commonly assumed that individual complexity is the origin of intricate social interactions. In primates for example, social complexity is attributed to their intelligence and it is argued by many that the cognitive capacity of primates are especially manifest in the way they regulate their social relationships. Whereas the complex societies of non-human primates are considered to be as a direct result of their cognitive abilities this assumption is not made about social insects. In the absence of certain cognitive abilities their complex societies and structurally sophisticated nests are thought to arise from self-organisation. Since it is unlikely that cognitive capacities are all-or-nothing, usually integrating a range of mechanisms, it is possible that different species use similar cognitive mechanisms resulting in different behavioural outcomes.

## Introduction

When observing and analysing complex systems, such as social structure, scientists tend to use separate explanations for each observed part or component of that system. Furthermore, they tend to explain the cause of complex patterns of behaviour observed at a higher lever (such as the relationship or the group) as if it resides within individuals, Hemelrijk (2004). In studies of social behaviour it is commonly assumed that individual complexity is the origin of intricate social interactions. In primates for example, social complexity is attributed to their intelligence and it is argued by many that the cognitive capacity of primates are especially manifest in the way they regulate their social relationships, Tomasello and Call (1997). In contrast, the complex organisations of social insects with large colonies and structurally sophisticated nests (honey bees for example) are not attributed to intelligence, their cognitive abilities are known to be limited and so any complex traits displayed are thought to arise from self-organisation, Hemelrijk and Puga-Gonzalez (2012). Explaining aspects of behaviour as different intelligent or rational decisions, leads scientists to come up with theories to integrate these separate aspects. The problem with such theories is that they tend to be complicated and assumption loaded. There are

considerably more possible reasons why cognitive capacity might not be found than there is evidence of their existence. Until such evidence is found the most parsimonious assumption should be that species, closely related or not, that show similar solutions to similar problems are likely to use similar cognitive mechanisms. It is therefore, theoretically possible that different species achieve similar outcomes in different ways and that unique outcomes do not always mean unique processes, de Waal and Ferrari (2010).

This paper describes an individual-orientated, agent-based model called *SimianWorld*. *SimianWorld* can be reasonably called an example of Artificial Life, *Artificial* because it is not designed to be in close correspondence with any previously observed life forms; *Life* because it expands our observable universe with entities who “live lives” in which we can observe patterns normally pre-eminently associated with real life, Hogeweg (1988).

As is typical for Artificial Life, the present study uses a bottom-up approach to generate hypotheses and alternative explanations for complex behaviour and social relationships in terms of simple behavioural rules, limited cognitive assumptions and environmental structure.

*SimianWorld* incorporates a simplified version of some aspects of animal behaviour and represents a kind of caricature. The advantage of a caricature is that by exaggerating patterns they become more visible, Hemelrijk (1999). In contrast to the naturally incomplete explanation of animal behaviour, *SimianWorld*'s complete description allows us to establish what factors and dynamics are responsible for the emergent social patterns. If patterns of behaviour happen to correspond to those observed natural systems new hypotheses for existing explanations may be derived from the model. Such hypotheses are often counter-intuitive and innovative.

## Non-Human Primates as Study Objects

To understand the role of positive and negative affect-based interactions in the formation of social relationships as a response to internal state and environmental conditions, non-human primates are good study objects. This is because the social organisation of many nonhuman primate species

relatively simple compared to that of humans but complex enough to be interesting. Primates have varied and diverse ways of expressing themselves socially and form various kinds of relationships. Furthermore, studies of non-human primates have illustrated the link between negative and positive affect-based interactions and social structure by relating dominance hierarchy to despotic and egalitarian societies.

From the observation that most primates live in groups, the rational deduction is that sociality must be a beneficial trait. The main advantage of group life is assumed to be protection, either against predators, van Schaik (1983) or against conspecific rival groups, Wrangham (1987). Competition plays an important but different role depending on your viewpoint. To van Schaik, competition for food with other group members is an inevitable consequence of group life and this, together with its benefits, determines optimal group size. Wrangham (1980; 1987), in contrast, sees competition between groups as the ultimate cause of sociality, in that large groups can displace smaller ones from vital resources. van Schaik combined within-group and between-group competition in an extended model, van Schaik (1989), to arrive at more detailed predictions on social relationships. He also added two different types of competition, contest competition, which occurs when individuals compete directly over resources, and scramble competition, which is based on the assumption that individuals lose resources because other group members have already used them. From the resulting combinations, van Schaik drew up a classification of primate social systems into competitive regimes. The matching types of social organisations in terms of “despotic” or “egalitarian” societies, Vehrencamp (1983), are then interpreted as predictions. For example, if ecological conditions lead to contest competition between groups, the formation of alliances will be important and therefore dominants must relax contest competition within the group. Otherwise subordinates might either refrain from taking any risks in between-group contests or even defect to another group, van Hooff and van Schaik (1992). Thierry et al. (2004) suggests that macaques are a particularly good model genus for studying the above model of primate social organisation. There are approximately 21 genetically closely related macaque species that can be classified both by diet (type of food available), distribution of food and by social relationships (despotic or egalitarian), Thierry (2006), van Hooff and van Schaik (1992).

### **Artificial Life Models of Primate Social Organisation**

te Boekhorst and Hogeweg (1994) used individual oriented models of “artificial apes” to study the formation of social groups based on simple gender differences in looking for food (by females) or females (by males). Limited manipulations of the rules and the environmental conditions lead to the emergence of chimpanzee-like or orangutan-like group

structures. The model thus arrived at alternative explanations for observed social structure without the need of either neo-darwinist assumptions about kinship selection, reciprocal altruism and optimal foraging theory or conjectures about sophisticated cognitive capacities. Hemelrijk (1999), has shown that dominance hierarchy, spatial social structure (with dominants in the centre of the group and subordinates at the periphery) and social organisation (despotic versus egalitarian societies) all emerged in an artificial world in which the behaviour of the agents was steered by only a few basic social rules (if lonely approach others, if others are too nearby either flee or chase them away), limited cognitive capacity (chase away another agent if its perceived dominance is lower than that of your own) and simple social dynamics (dominance of an individual increases especially if it wins by accident against expectation). The model also resulted in similarities and new insights about the relationship between aggressive behaviour, dominance and social structure as found in the macaque species studied by Thierry.

In summary, the above mentioned Artificial Life models studied either the effect of food type and food distribution on the composition of groups, but did not address social relationships, te Boekhorst and Hogeweg (1994) or they studied the emergence of social relationships and structures based on dominance interactions but without modelling food resources, Hemelrijk (1999). As such they incompletely addressed the framework of van Schaik (1989). One of the objectives of this research is to combine the social aspects of the Hemelrijk model with ecological resources modelled by te Boekhorst and Hogeweg (1994).

### **Higher-levels of Affective States**

The above mentioned Artificial Life models adopt a very simple implementation of affective states and affect-based interactions (mainly leading to group members moving away or staying close to other agents). However, in real life affective states are more complex and include for example emotions, drives, pleasure, pain, attitudes, moods and values. At this point it is important to distinguish between motivations and emotions. Motivational states such as hunger and thirst, for example, are drives that constitute urges to action based on internal needs related to survival and are seen as homeostatic processes which maintain a controlled physiological variable with a certain range. Emotions however, can be regarded as second-order modifiers or amplifiers of motivation, Cañamero (1997). Neurobiology attempts to characterise emotions as complex reflexes that regulate control mechanisms to excite or inhibit response to stimuli - both internal and external.

Motivational and emotional mechanisms have been attributed with complementary roles - while motivation is concerned with the operations of appetitive processes that try to activate action as a response to deprivation, emotion is derived from processes that try to stop ongoing behaviour

i.e. it is concerned with satiation and equilibrium, Cañamero (1997). Disciplines as diverse as psychology, neurobiology, and philosophy have studied the nature of emotions. These diverse disciplines have focused on different aspects of emotional phenomena, sometimes proposing incompatible theories about them. However, they all share the same underlying idea: that emotions, whatever they are, have an adaptive value – they serve a purpose. This hypothesis is known as the functional view of emotions, Cañamero (2001). Attempts to integrate higher level affective states into agent architectures has been receiving increasing attention in Artificial Life and Cognitive Science. Proposed reasons for this, Cañamero (2001), are that affective agent-based systems can be used in the following ways:

1. As a test bed for theories about affective states in animals and humans, a synthetic approach that complements analytical studies of natural systems.
2. To explore the role that affective states plays in biology in order to develop and exploit mechanisms that ground and enhance autonomy, adaptation and social interactions.

### Implementation of Affective States in the SimianWorld Model

The *SimianWorld* agent architecture consists of motivational states and behaviours. There are two homeostatic variables that correspond to the internal resources of energy and sociability. Together these variables represent the internal state of an agent and each has an “ideal state” (i.e. a set point or norm value). The degree to which each variable deviates (the error) from this ideal state constitutes internal stimuli and directly influences agent behaviour. The agent’s motivational states are abstract representations of a propensity to behave in a particular way as a result of a combination of internal and external stimuli.

### The Agent Architecture

External stimuli comes in two forms, the first of which is clumps of food. By eating the food agents modify both the external environment and their own internal level of energy. The other type of stimulus is the agents themselves. The presence of other agents stimulates social behaviours (like groom and attack for example) that modify the agent’s internal level of sociability.

So, the motivational state is the mechanism that corrects the level of error in the homeostatic variables representing physiology through the execution of appropriate behaviours. How the agents react in social situations such as eating or resting for example, and how they interact, will largely depend on the distribution pattern of food (the amount, distribution and renewal rate of food can be closely controlled). Interactions can be of either a positive nature, like grooming for instance or be negative in nature, as in the case of an

attack. When calculating motivation intensity and thereby activating a behaviour it is fundamental to define a rule combining external and internal stimulus. *SimianWorld* uses the following method:

1. The motivation  $j$  is calculated in the following way: For each motivation  $j$ :
  - i Calculate the intensity of the motivation’s drive, proportional to the error of its homeostatic variable  $v(e_{v_j} \in [0, 1])$
  - ii Calculate the effect of the presence of external stimuli  $k$  influencing the intensity of the motivation  $j$  (an increased incentive):  $s_{k_j} \in [0, 1]$
  - iii  $m_j = e_{v_j} + (s_{k_j} \times e_{v_j})$  is the final intensity of  $j$

The motivation with the highest intensity is selected and an appropriate behaviour activated.

2. The error is calculated in the following way:
  - i Calculate the distance between the set point and the limit:  $ld_v = abs(l_v - p_v)$
  - ii Calculated the distance between the actual variable and the set point:  $vd_v = abs(v_v - p_v)$
  - iii Calculate the normalised error

$$e_v = \begin{cases} vd_v/ld_v & \text{if } ld_v > abs(l_v - v_v) \\ 0 & \text{otherwise} \end{cases}$$

The way in which motivation and behavioural intensity are combined is a problem that has been extensively researched by ethologists. *citetA24* demonstrated that a simple adaptive rule,  $Cue \times Deficit$ :  $m_j = s_{k_j} \times e_{v_j}$  gives the behaviour of an agent both opportunism and persistence.

The problem with this rule is the lack of motivational arousal in the absence of external stimuli. This model would prove fatal in models in which the motivational state leads to the selection of appetitive<sup>1</sup> behaviours.

Therefore *SimianWorld* uses the following extension to the formula proposed by Tyrrell (1993):

$$Deficit + Cue \times Deficit: m_j = e_{v_j} + (s_{k_j} \times e_{v_j})$$

<sup>1</sup>Animal searching behaviour. The variable introductory phase of an instinctive behaviour pattern or sequence, e.g., looking for food or looking for others.

Behaviour	Homeostatic Variables	
	Energy	Sociability
Eat	↑	with others ↑ alone ↓
Groom (source)	↑	↑
Groom (target)	↓	↑
Attack (source)	↓	↓
Attack (target)	↓	↓
Find Others	↓	↓
Find Food	↓	↓
Wander	↓	↓
Avoid	↓	↓
Rest	↓	with others ↑ alone ↓

Table 1: Behaviours and their Effect on the Homeostatic Variables

Using the above method agents select a behaviour most likely to satisfy their immediate needs. For instance an agent whose energy level is satisfied (above the set point or norm value) but whose level of sociability is low may seek other agents (Find Others). However, finding others uses energy and at some point the agent may need to alter its behaviour. Every agent's levels of energy and sociability are calculated at each time tick, time ticks are regulated using the GetTick-Count function in C++ which returns the system time in milliseconds. The sequence in which each agent is scheduled to activate its selected behaviour is reordered at each time tick.

Agents in *SimianWorld* are “individuals” possessing a behavioural repertoire that includes sensing their local environment, changing the environment and changing their own position in the environment. Each agent is initialised with the set point values of energy and sociability, in addition they are given a random starting position on the grid and a random direction. The grid squares that immediately surround each agent are designated as personal space with a further number of grid squares designated as their vision range, see Figure 1. The behaviours modelled by *SimianWorld* are: eat, attack, groom, wander, rest, find food, find others and avoid others, see Table 1.

### The System Architecture

The system architecture has two elements; the agents and a simple ecology. The agents are homogeneous and live in a flat, boundary restricted world, their territory. The landscape has no features apart from clumps of food. The size of the territory can be altered but for the all the simulations

Figure 1: Snapshot of agents in *SimianWorld*

run to date this has been set to the maximum size of 130 x 115 (14950 grid locations). Agents can move in any direction – randomly chosen when the boundary is reached. The amount and distribution of food can also be closely controlled through the interface, as can the population size and vision range of the agents. There is a full graphical display of the simulated environment that shows the agents (displaying their field of vision is optional but is costly in terms of visual rendering) position within the grid and the location of food clumps, see Figure 2.

Figure 2: The Graphical Interface

### Experimental setup

As a first experiment, we investigated the possible relationships between on the one hand measures of distribution and amount of food and on the other hand the reciprocation of dominance interactions (as a reflection of negative affect) and friendship interactions (as a reflection of positive affect). Reciprocation was crudely measured as the correlation coefficient between row and column totals of “dominance” and

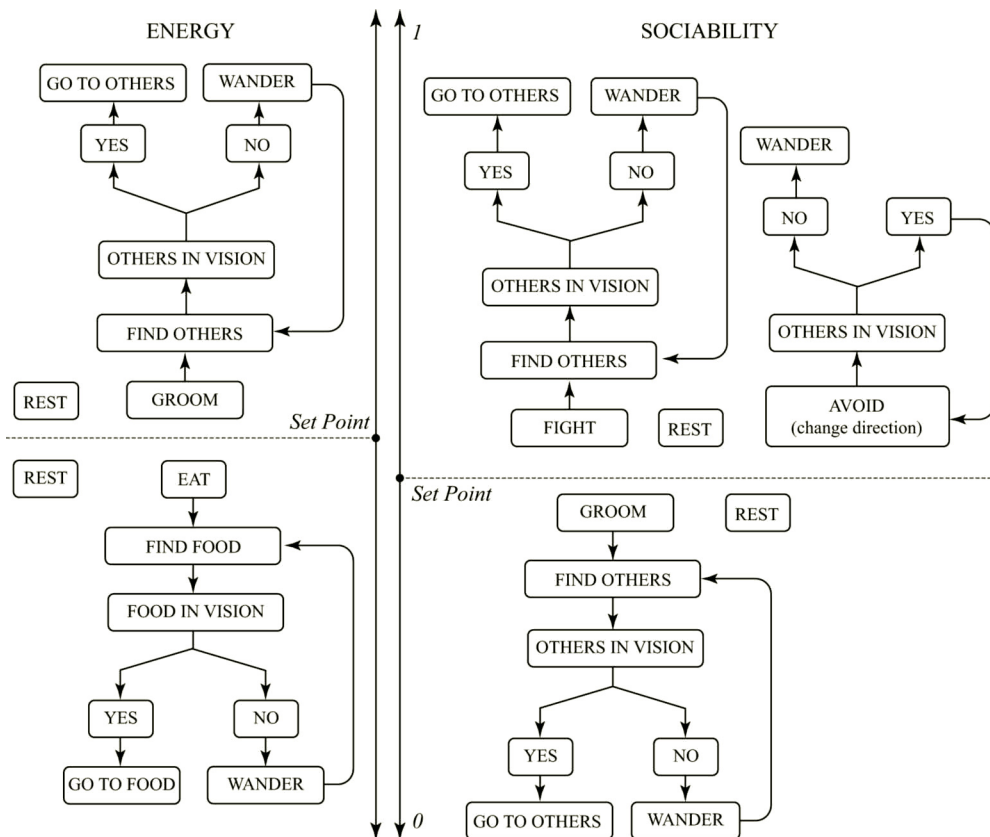

Figure 3: The SimianWorld Architecture

“friendship” matrices. These correlation coefficients were calculated for the following environmental conditions:

1. A large amount of food highly clumped
2. A small amount of food highly clumped
3. A large amount of food widely distributed
4. A small amount of food widely distributed

The distribution of food in clumps is calculated in a very simple way, the amount of food (set to between 1 and 500 grid squares occupied by food) is divided by the distribution level of food (set to between 1 and 25). Thus, 400 grid squares of food, divided by a distribution factor of 5 produces 5 clumps of food in 80 grid squares. At the start of a simulation, each clump begins at a randomly chosen grid square about which the required number of grid squares of food are closely grouped. Food is “consumed” by agents and can be renewed, rejoining a previously established clump at set time intervals (ticks). All the above mentioned variables are set at the start of a simulation run through an Options panel in the interface. The renewal rate of food is dependent

on each combination in order to maintain initial conditions where possible.

For each of the 4 environmental conditions 5 runs were conducted with a population of 10 agents and 5 runs with 20 agents (40 runs in total). Each run consisted of 26010 time ticks and at every time tick each agent’s internal state was assessed and an appropriate behaviour executed. During each run and at every time tick the agent’s spatial position, behaviour, levels of sociability and energy were recorded. In addition, at intervals of 600 time ticks during the run a log was taken of all the positive and negative interactions and these were stored in the form of a matrix.

Each time two agents meet, their interactions were characterised as either negative or positive and these outcomes are summarised respectively in a “dominance” and a “friendship” matrix. The values of the cells in the matrix, reading from left to right, are the frequencies by which a row-labeled agent initiated an interaction with a column-labeled agent. Reading from top to bottom, the values are the frequencies by which a column-labeled agent received an interaction from row-labeled agents.

Accordingly, row-totals are the total frequencies agents

started interactions irrespective the identity of the receivers, and column-totals are the overall count of interactions agents received (summed over all the initiating agents). In this sense a positive correlation between row and column totals implies that agents that initiated more interactions also received more of those interactions and thus functions as a crude measure for reciprocity.

## Results

Although there were four different environmental conditions each tested with both large and small populations only some produced results that could be considered interesting. Interesting in the sense that the emergent social patterns indicated either despotic or egalitarian social structures.

1. With a large amount of food and a small population (10), negative reciprocation of dominance interactions implies agents initiate a greater number of “aggressive” interactions than they receive. Thus indicating a more “despotic” social structure. See Figure 4.
2. With large clumps of food and a large population (20) there is a negative reciprocation of dominance interactions. This implies that under these conditions agents *tend* to initiate more “aggressive” interactions than they receive. Indicating a more “despotic” social structure (results are not significant  $p = 0.06$ ). See Figure 5.
3. With a low amount of food and a large population (20), negative reciprocation of friendship interactions implies agents tend to initiate a greater number of “friendly” interactions than they receive (results are not significant  $p = 0.09$ ). See Figure 6.

## Conclusion

Models of Artificial Life have in the past been used to study the effect of food type and food distribution on the composition (fission/fusion) of groups, te Boekhorst and Hogeweg (1994), but did not include any details of social relationships. They have also been used to study the emergence of social relationships and structures based on dominance interactions but without modelling food conditions, Hemelrijk (1999). The main objective of this research is to combine aspects of social relationships and ecological resources in one model and to study the structure of the societies that emerge.

One specific aim of this research is to relate the results of future tests to that of social structures found in nature (macaques).

Work to date has concentrated on building an individual-orientated, agent-based software prototype (Simian World) that uses an Artificial Life approach that incorporates a simplified version of some aspects of animal behaviour. In contrast to the naturally incomplete explanations of animal behaviour, the model's complete description allows us to estab-

Figure 4: Analysis of Dominance Reciprocity under 4 Environmental Conditions (small population)

lish what factors and dynamics are responsible for emergent social patterns.

If patterns of behaviour happen to correspond to those observed natural systems new hypotheses for existing explanations may be derived from the model. Such hypotheses are often counter-intuitive and innovative. SimianWorld studied the impact of food availability (profuse/scarse) and distribution (clumped/dispersed) on the types of affective, dyadic relationships agents developed. This was based on the hypothesis that competition for resources in an environment influences the types of society (egalitarian or despotic) that emerge - results were statistically significant for reciprocity of social relationships when there is a large amount of food available and the population is relatively small. Negative reciprocation of dominance interactions implied that agents initiated a greater number of aggressive interactions than they received indicating a more despotic social structure. It is planned to include in the model a second order modifier in the form of a hormone-like mechanism. This will introduce a more biologically plausible sigmoid rather than a linear decrease/increase of the levels of energy and sociability, and will be designed to influence levels of aggressive versus friendly behaviour which characterise the types of social relationship of egalitarian or despotic societies. It is hoped that results will show statistical significance in tests for reci-

## Abstract

We propose the use of an exploratory self-organised policy to initialise the parameters of the function approximation in the reinforcement learning policy based on the value function of the exploratory probe in a low-dimensional task. For a high-dimensional problems we exploit the property of the exploratory behaviour to establish a coordination among the degrees of freedom of a robot without any explicit knowledge of the configuration of the robot or the environment. The approach is illustrated by a learning tasks in a six-legged robot. Results show that the initialisation based on the exploratory value function improve the learning speed in the low-dimensional task and that some correlation towards a higher reward can be acquired in the high-dimensional task.

## Introduction

Reinforcement learning aims at solving dynamical optimisation problems which may be formulated in terms of discrete or continuous variables (Sutton, 1988; Sutton and Barto, 1998; Doya, 2000). It is based on an utility function and/or the construction of a control policy such that optimal performance can be reached asymptotically under certain conditions. Particularly, in continuous time and space the use of function approximation is imperative to match the complexity of the problem. Various techniques have been proposed in order to approximate the relevant functions, e.g. kernel-based methods (Xu et al., 2007; He et al., 2011), normalised Gaussian networks (Sato and Ishii, 2000; Doya, 2000), Fourier basis function (Konidaris et al., 2008) and echo state networks (Jaeger, 2001; Szita et al., 2006).

The initialisation of the parameters of the function approximator becomes non-trivial when — as in most robotic tasks — a high learning speed is required. Ideally, the initialisation should be such that the learning trajectory can follow the gradient without being trapped in undesired optima. Often, the approximator is initialised by small random values, which in some cases aids the exploration of the state and action space. Other approaches assign optimistic value to every position of the state space which also provides an initial incentive to explore until values in a more realistic range are found. Often, however, these value will not be

close to the true expected future rewards, because the optimistic values decay linearly while sufficiently exploration takes usually longer, such that, at least in the more complex problems, more flexible exploration strategies are worth being considered.

We propose a self-organising exploration mode that will discover coherent behaviour in a robot in an autonomous learning stage before reward signals are used or are available. This behaviour will be used here to pre-shape the parametric representation of the policy in an actor-critic reinforcement learning scheme. The exploration method produces an on-policy estimate of the value function, such that its value can be a good indicator of how well the robot will perform in a specific task later if only the promising actions of the policy are used. The exploration will in particular introduce a bias that can reduce the complexity of the problem by using information that was inexpensively obtained earlier. In our robotic application this means that the robot preferentially guided to regions in the state space where controllability and predictability of the dynamics is high.

Nevertheless, function approximation does not easily generalise to high dimensions unless independence or hierarchical structures can be assumed. In robotic problems as well as in biological examples, however, such assumptions are rarely justified, i.e. often the exploitable structure is not explicitly known. As the main contribution of this study, we propose a combination of homeokinetic and reinforcement learning which uses for high-dimensional reinforcement learning tasks a combination of autonomous exploration with a reward-weighted extraction of information.

In the case that the exploitable structure is known in advance, a similar effect has been shown before (Martius and Herrmann, 2011). In this study, it was shown for a track-like robot (“armband”) that the learning time can decrease even for an increase of the mechanical complexity of the robot if the complexity of the control problem was relatively low. The reason for this observation was in addition to the built-in interaction structure that the robot was less likely to self-obstruct in the high-dimensional case. The speed-up saturated at a few tens of dimensions and the remaining learning

time was low due to the homogeneity of the robot's configuration. Here we will study a more complex problem, namely a hexapod with twelve degrees of freedom which require a measure of coordination for ambulation or navigation.

The ambivalence of training and self-organisation reflects an important principle in biological learning. Although in many cases the external event distribution is sufficient to drive learning successfully, there are often intrinsic mechanisms available as a more or less equally successful fall-back option which the organism can rely on when the environment deviates from the evolutionarily anticipated standard. We will not discuss, how the organisms deal with the unfortunate latter case, but with the potential benefits of a preparation before environmental reward signals are available or while they are not yet critical such as in play in a protected environment. In addition to this consideration and particularly in robotic applications, the prior-learning scheme can add naturalness to the movements and simplify the search space when the purposeful movements are to be learned subsequently.

The early-learning algorithm relies on a self-organising control paradigm (Martius et al., 2007). This controller creates coherent exploratory behaviour by maximising the predictability of the robot action at the same time that it tries to maximise the sensitivity of each motor command. In order to propagate the best actions from the exploratory mode to reinforcement learning, we let the value function to be learned by the critic while the actor is fixed to the exploratory policy. The on-policy property of the actor-critic algorithm, i.e. the fact that the value function is learned based on the actual policy, makes this method suitable to assess the performance of the exploratory regime. In a first low-dimensional experiment the exploration policy is propagated directly to the actor's policy when the value function is positive. For negative values of the value function we propagate the opposite actions. In reinforcement learning the value function invokes the beneficial actions but it gives us little information about where to explore next if its value is not sufficient for the task. Another experiment is realised with a high-dimensional case. In order to overcome the curse of dimensionality, a closed-loop controller is learned which can function similar to a central pattern generator (CPG), where its coordination factors are shaped following the instantaneous reward.

We present a comparison of our approach with a standard version of continuous reinforcement learning (Doya, 2000) in low-dimensionality, whilst in high-dimensionality the direct reward is used to propagate the correlation between the degrees of freedom. The reward of the tasks is the horizontal speed of a six-legged robot.

## Reinforcement learning in continuous domains

For continuous reinforcement learning (Doya, 2000), we will have to adjust the weights  $w^A$  that determine the output

$u$  of a controller  $U$  which is given by

$$u_t = U_t(x_t) = s(A(x_t; w^A) + \sigma n_t), \quad (1)$$

where  $s$  is usually a sigmoidal or an identity output function,  $n$  is a probing input signal of strength  $\sigma$  and

$$A(x_t; w^A) = \frac{1}{N(x_t)} \sum_i w_i^A \exp\left(-\frac{\|x_t - \mu_i\|^2}{2\rho_i}\right) \quad (2)$$

represents the approximator function with parameter  $w^A$  of the actor's policy. The values of  $\rho_i$  and  $\mu_i$  represent the size and centre of a basis function, here are assumed to be fixed. The factor  $N(x_t) = \sum_i \exp\left(-\frac{\|x_t - \mu_i\|^2}{2\rho_i}\right)$  normalises the output. The parameters  $w^A$  are updated according to

$$\dot{w}_i^A = \varepsilon_A \delta_t n_t \frac{\partial A(x_t; w^A)}{\partial w_i^A}, \quad (3)$$

where  $\varepsilon_A$  is the actor's learning rate. The last term in Eq. 3 can be obtained directly from the explicit form of the policy in Eq. 2. The essential part of the learning rule includes the correlation of the probing input  $n$  and the delta error,

$$\delta_t = r_t - \frac{1}{\tau} V_t + \dot{V}_t, \quad (4)$$

where  $r_t$  is the instant reward at time  $t$ ,  $\tau$  is the time constant for discounting future rewards and the utility function  $V$  is approximated by another parametrised function which is updated based on the approximation of the critic by the relation

$$\dot{V}_t \cong (V_t - V_{t-\Delta t})/\Delta t$$

which can be obtained from Eq. 4. The update of the parameter  $w_i^V$  of  $V$  follows the gradient descent with respect to  $\delta$ ,

$$\dot{w}_i^V = \varepsilon_V \delta(t) \frac{\partial V(x_{t-\Delta t}; w^V)}{\partial w_i^V}, \quad (5)$$

with  $\varepsilon_V$  learning rate.

The alternatives for choosing the probing signal of the robot control in Eq. 1 range from the use of noise (Gullapalli, 1990) to high-frequency oscillatory modulations of the motor command (Wiener, 1948). Our experiments (Smith and Herrmann, 2012) confirm that the type of the probe does not matter in low-dimensional problems. The dynamics of the correlation among the degrees of freedom of the controlled system becomes crucial for robots with many degrees of freedom, such that the choice of the probing stimulus becomes non-trivial. In high-dimensional problems it is not possible to test all actions in all states infinitely often as it would be required in discrete reinforcement learning algorithms. Also for continuous algorithms orienting the exploration to promising directions is essential. We propose to use an approach in the present context that has previously developed in a different setting (Martius, 2010).

## Learning in motor space

As exploration signal we propose the exploratory controller

$$\mathbf{y}_t = K(\mathbf{x}_t) = g(C\mathbf{x}_t + \mathbf{c}). \quad (6)$$

This controller receives the current sensory input vector  $\mathbf{x}_t \in \mathbb{R}^n$  and determines the direction of exploration in dependence on the multidimensional parameters  $C \in \mathbb{R}^{m \times n}$  and  $\mathbf{c} \in \mathbb{R}^m$  and the nonlinear function  $g$ , where  $\mathbf{y}_t \in \mathbb{R}^m$ . In order to adapt the parameters  $C$  and  $\mathbf{c}$ , the new sensory inputs are compared with a prediction  $\hat{\mathbf{x}}_t \in \mathbb{R}^n$  by a world model  $M$  based on previous inputs or outputs. For simplicity, we use a linear predictor that uses only the motor commands from Eq. 6 and receives thus information about previous inputs only indirectly,

$$\hat{\mathbf{x}}_{t+1} = M(\mathbf{y}_t) = D\mathbf{y}_t + \mathbf{d}, \quad (7)$$

where  $D \in \mathbb{R}^{n \times m}$  and  $\mathbf{d} \in \mathbb{R}^n$ .

The comparison of the corresponding sensory input  $\mathbf{x}_{t+1}$  and its estimate by the internal model  $\hat{\mathbf{x}}_{t+1}$  results in the prediction error  $\boldsymbol{\xi}_{t+1} = \hat{\mathbf{x}}_{t+1} - \mathbf{x}_{t+1}$  which is a vector in the perceptual space where  $\boldsymbol{\xi}_t \in \mathbb{R}^n$ .

In order to formulate a learning rule for the exploratory controller of Eq. 6, we will follow the procedure in (Martius, 2010) and express the error in the motor space which can be achieved by defining a transformed error  $\boldsymbol{\eta}_t \in \mathbb{R}^m$  via

$$M(\mathbf{y}_t) + \boldsymbol{\xi}_{t+1} = M(\mathbf{y}_t + \boldsymbol{\eta}_t). \quad (8)$$

Because  $M(\mathbf{y}_t) + \boldsymbol{\xi}_{t+1} = \mathbf{x}_{t+1}$ , the motor error  $\boldsymbol{\eta}_t$  can be interpreted as the control correction required to compensate the inaccuracy of the model  $M$ . The vector  $\boldsymbol{\eta}_t$  is a retrospective error that can be determined only after the event of receiving the new stimulus  $\mathbf{x}_{t+1}$ . Nevertheless, minimisation of  $\boldsymbol{\eta}$  is a relevant goal for the adaptation of the system. The definition in Eq. 8 is implicit and may be empty which calls for the use of a regularised inverse of  $M$  to explicitly obtain an approximation of  $\boldsymbol{\eta}$ . Practically, Eq. 8 is transformed into a motor level error exploiting the assumed linearity of the model in Eq. 7,

$$\boldsymbol{\eta}_t = M'^+ \boldsymbol{\xi}_{t+1}, \quad (9)$$

where  $M'^+$  is the pseudo-inverse of the derivative of the model in Eq. 7, i.e. the pseudoinverse of  $D$ . In analogy to (Der et al., 2002) this defines a homeokinetic error function in the motor space

$$E_t = \boldsymbol{\eta}_t^\top (J_t J_t^\top)^{-1} \boldsymbol{\eta}_t \quad (10)$$

where  $J$  is the Jacobian of the sensorimotor loop, see below. We are going to perform a gradient descent with respect to this error function in order to adapt the parameters of the controller defined in Eq. 6.

To calculate the Jacobian, we use the derivatives  $M'_y = D$  and  $K'_x = g' \circ C$ , with  $\circ$  defined as element-wise multiplication, such that we find from  $J_t = g'_t \circ C_t D_t = g'_t \circ R_t$ , with  $R_t \in \mathbb{R}^{m \times n}$  and  $R_t = C_t D_t$ . This gives rise to the following formulation of the shift  $\boldsymbol{\nu}$ , i.e. the change in motor command that would have been required to correctly predict the following motor command, namely

$$\boldsymbol{\nu}_{t-1} = J_t^{-1} \boldsymbol{\eta}_t.$$

While the interpretation of  $\boldsymbol{\eta}$  (Eq. 9) as retrospective error connects sensor and motor space, we have here a connection between the two points in time within the motor space that reflects the dynamical properties of the full sensorimotor loop. The error function in Eq. 10 becomes thus simply

$$E_t = \boldsymbol{\nu}_{t-1}^\top \boldsymbol{\nu}_{t-1}$$

which lead to a convenient update rule of the controller matrix  $C$ . Omitting the time indices we find

$$\begin{aligned} \frac{1}{\varepsilon_C} \Delta C &= -\frac{\partial E}{\partial C} = -2\boldsymbol{\nu}^\top \frac{\partial \boldsymbol{\nu}}{\partial C} \\ &= 2\boldsymbol{\nu}^\top J^{-1} \frac{\partial J}{\partial C} J^{-1} \boldsymbol{\eta} - 2\boldsymbol{\nu}^\top J^{-1} \frac{\partial \boldsymbol{\eta}}{\partial C} \end{aligned}$$

using the rule  $\frac{\partial Y^{-1}}{\partial X} = -Y^{-1} \frac{\partial Y}{\partial X} Y^{-1}$ . The derivative  $\frac{\partial \boldsymbol{\eta}}{\partial C}$  cannot be determined, because we have no information of the dependence of the prediction error on the controller parameters, therefore we set  $\frac{\partial \boldsymbol{\eta}}{\partial C} = 0$  and are left with

$$\frac{1}{\varepsilon_C} \Delta C = 2\boldsymbol{\nu}^\top J^{-1} \frac{\partial J}{\partial C} J^{-1} \boldsymbol{\eta} = 2\boldsymbol{\nu}^\top J^{-1} \frac{\partial J}{\partial C} \boldsymbol{\nu}$$

where

$$\frac{\partial J_t}{\partial C} = \frac{\partial}{\partial C} \left( \frac{\partial D}{\partial \mathbf{x}} + g'_t \circ C_t \right) D_t.$$

We may ignore the effect of the controller on the sensitivity of the actor in the reinforcement learning component, i.e. set  $\frac{\partial}{\partial C} \frac{\partial D}{\partial \mathbf{x}} = 0$ . We may also assume that the details of the actor are not specified by the reward but will follow essentially the homeokinetic control. In this case the term  $\frac{\partial}{\partial C} \frac{\partial D}{\partial \mathbf{x}}$  is parallel to the remainder and the resulting numerical factor can be absorbed into the learning rate. We have thus arrived at essentially the same learning rule as in (Martius, 2010),

$$\frac{1}{\varepsilon_C} \Delta C = \boldsymbol{\chi} (D\boldsymbol{\nu})^\top - \boldsymbol{\chi}^\top \frac{\partial g'^{-1} \circ \boldsymbol{\eta}}{\partial C},$$

where  $\varepsilon_C$  is a learning rate and  $\boldsymbol{\chi} \in \mathbb{R}^m$  as  $\boldsymbol{\chi} = R^{-1\top} \boldsymbol{\nu}$ .

Inserting the correct time indexes we obtain

$$\begin{aligned} \frac{1}{\varepsilon_C} \Delta C_t &= \boldsymbol{\chi}_{t-1} (D_t \boldsymbol{\nu}_{t-2})^\top \\ &\quad - 2(\boldsymbol{\chi}_{t-1} \circ g_{t-2} \circ (g'_{t-2})^{-1} \circ \boldsymbol{\eta}_{t-1}) \boldsymbol{\chi}_{t-2}^\top, \quad (11) \end{aligned}$$

with  $\chi_{t-1} = (R_t^\top)^{-1} \nu_{t-2}$ . The update rule for  $c$  can be found similarly,

$$\frac{1}{\varepsilon_C} \Delta c_t = -2 \left( \chi_{t-1} \circ g_{t-2} \circ (g'_{t-2})^{-1} \circ \eta_{t-1} \right). \quad (12)$$

### Direct learning of the actor

The exploratory controller presented above can provide a variety of coherent behaviours based solely on the interaction of the agent and its environment. We propose that such behaviours can be used to shape the action space for an actor-critic reinforcement learning problem by shaping the structure of the search space.

Initially, the agent is controlled by the homeokinetic controller (Eqs. 6, 11 and 12) giving the motor signal to the agent and also shaping the action space. Following homeokinetic motor command in Eq. 6, the implementation of the actor in reinforcement learning shown in Eq. 2 with learning rule from Eq. 3, the difference between the actual motor command and the actor's output  $e_t^A \in \mathbb{R}^m$ ,  $e_t^A = \mathbf{y}_t - A(\mathbf{x}_t; \mathbf{w}^A)$ , gives rise to the objective function,  $E_t = \frac{1}{2} \|e_t^A\|^2$ . The weights  $\mathbf{w}^A$  of the actor's approximator are updated with a gradient descent algorithm,  $\dot{w}_i^A = -\varepsilon_H \frac{\partial E}{\partial w_i}$  with  $\varepsilon_H$  the learning rate.

After the adaptation, the function approximator has stabilised, the reinforcement learning algorithm is activated and the policy calculated from the actor following Eq. 1, and the actor's parameters are updated based on Eq. 3 using random noise as probing signal.

Figure 1: Simulated robot in the lpzrobots simulation environment. The design of the robot is inspired by M. C. Escher's lithograph *Wentelteefje* (1951).

### Self-organisation for parameters initialisation

In order to test the described approach, we will study a low-dimensional control problem for a simulated six-legged robot, see Fig. 1. Switching from the initialisation mode to reinforcement learning is triggered by the amplitude of the error in the approximation which is required to be below a threshold for a certain time. The propagated values from the self-organised policy to the initialisation of the actor's policy

is directly translated when the value function has a positive value as this part of the policy already shows the suitability to perform the task. When the value function is negative we propagate the opposite values of the self-organised policy. The justification for this is that the reward only tells what is a beneficial (we want to propagate) and what is not (we only know that this behaviour should not be propagated), since we have all the action state to choose from (except from the actual not beneficial behaviour) we assume that the opposite of the actual command is a better guess than a random action. This will carry the coherence found by the probing but in the opposite direction in our servo motor robot. To illustrate this point we present a toy example where the reward is directly related to the y-axis position of one leg of the robot. In Fig. 2a, the random initialisation of the reinforcement learning policy can be seen, in Fig. 2b, the shape of the exploration signal, in the Fig. 2c, the value function of derived from the exploration policy and in Fig. 2d, the propagated values from the exploration signal to the initial conditions of the actor's policy. The values of the exploration signal that have positive (blue) value function are propagated directly while the exploration signal with negative (red) value function is inverse propagated.

Figure 2: Shape of the approximation of the actor. The x-axis of the position of the leg is represented in the horizontal axis, the y-axis is represented in the vertical axis. For (a), (b) and (d) the colour represents a motor command with blue values closer to 1 and red values closer to -1; for (c) the colour represents the value function with same range. Figure (a) represents the random initialisation, (b) is learned from the homeokinetic controller, (c) is the value function and (d) the initialised actor's policy based on the exploratory signal following the value function. It can be seen how the propagated values from (b) to (d) depend on (c).

In the low-dimensional set-up the task of the robot will be to walk forwards as fast as possible and the rewards will be directly proportional to the absolute value of the velocity of the centre of mass of the robot. A virtual leg is trained and will form a CPG whose motor signal is transmitted to the rest of the limbs either as an in-phase or as an anti-phase signal. While the random initialisation in of the two degrees of freedom may lead to local minima or slow convergence, a smoother function is brought about due to the training with the homeokinetic controller. This may allow for a faster learning once the information about the task is available by the reward signal.

The results shown in Fig. 3 demonstrate that the homeokinetic learning indeed improves the performance in the learning task.

Figure 3: Results of reinforcement learning with random initialisation (red continuous line) of the parameters and with parameters shaped by homeokinetic controller (green dashed line). The six-legged robot receives reward based on horizontal speed. For the green dashed curve the first 600 seconds (shown as the first 120 point of averaged speed over 5 seconds) are used to pre-train the robot, i.e. no reward is available, which can be seen in detail in the inset. With the homeokinetic pre-training, the time to achieve the highest velocity achievable by reinforcement learning is significantly decreased. If the two systems continue to learn for much longer times, our experiments show that both arrive at a very similar reward level.

The basis for the comparison is the reinforcement learning initialised with random weights in the function approximator. An increment in the learning speed can be noticed as a result of the exploratory learning due to homeokinetic control.

### Reward-weighted correlation

A more flexible method will be discussed in the following as a generalisation of the previous approach. At the same time we generalise the variants in (Martius and Herrmann, 2012) by including the reward signal in the extraction of the interaction structure. We consider the correlation between sensory inputs and motor commands,

$$W_{ij} = \frac{\langle (x_{i,t} - \langle x_i \rangle)(y_{j,t} - \langle y_j \rangle) \rangle}{\sqrt{\langle (x_{i,t} - \langle x_i \rangle)^2 \rangle \langle (y_{j,t} - \langle y_j \rangle)^2 \rangle}}, \quad (13)$$

where  $\langle \cdot \rangle$  denotes a sliding temporal average with time constant  $\tau_W$ . Eq. 14 can be transformed into a reward-related quantity by an appropriate weighting based on the rectified

reward signal  $r^{[+]}$ .

$$W_{ij,t}^{r^{[+]}} = \frac{\langle r_t^{[+]}(x_{i,t} - \langle x_i \rangle)(y_{j,t} - \langle y_j \rangle) \rangle}{\sqrt{\langle (r_t^{[+]} - \langle r^{[+]} \rangle)^2 \rangle \langle (x_{i,t} - \langle x_i \rangle)^2 \rangle \langle (y_{j,t} - \langle y_j \rangle)^2 \rangle}}, \quad (14)$$

As before the reward signal  $r$  is determined by the forward speed of the centre of mass of the robot. The factor  $r^{[+]}$  equals  $r$  for positive forward speed and is zero if the robot is actually moving backwards. In this way only those sensori-motor couplings that directly contribute to the reward enter the average. The control weights are a smoothed version of the result of Eq. 15.

$$\bar{W}_{ij,t+1} = \varepsilon_W W_{ij,t}^{r^{[+]}} + (1 - \varepsilon_W) \bar{W}_{ij,t}. \quad (15)$$

where  $\varepsilon_W < 1$  is the adaptation rate.

### Learning gait patterns in a hexapod

In the high-dimensional task, instead of learning with a classic reinforcement learning approach we try to discover the correlation between the different degrees of freedom based on the instantaneous reward. The exploration is produced by the homeokinetic controller and the learning rule is based on Eq. 16. In the following experiment we compare the results obtained from the behaviour of the robot for differently obtained controller matrices in a close-loop setting. Closed-loop feedback control is realised by a controller output related to the current input via  $y_t = Hx_t$ , where  $x_t$  and  $y_t$  are the input sensors and output motor commands vectors respectively. In the first case served as a baseline, the matrix  $H$  is obtained from a hand-crafted CPG matrix that was designed to control the robot in a smooth and highly rewarded fashion. The CPG matrix can be used to perform an open-loop control of the robot, but by a minor phase shift it functions also in closed-loop. In the second case the feedback matrix was learned from the correlations observed in the first case (Eq. 14), i.e. without taking the reward in consideration, while in the third case the matrix was learned by the robot while exploring based on a homeokinetic controller. The three matrices are shown in Fig. 4, where the sensor inputs are presented as rows and the motor commands as columns. All matrices are scaled appropriately such that resting state becomes unstable and the legs of the robot start to move.

In order to characterise the behaviour generated in these cases we show in Fig. 5 the behaviour of one leg of the robot with its  $x$  and  $y$  position. Fig. 6 is added to show the phase relations between the two degrees of freedom for one leg. The CPG-style matrix produces the desired behaviour for the legs with a tripod gait and maximising the use of the leg state space. The second matrix inherits from the behaviour of the first case a consistent relation between the degrees of freedom, however, the matrix is blurred due to hardware-induced deviation from the ideal interaction matrix. In some cases white boxes representing the absence of a correlation,

Figure 4: The matrix on the left contains the coefficients similar to a coupled CPG, which is sufficient to perform a tripod gait. With the small changes this matrix can also be used as a closed-loop controller. The matrix on the middle has been learned by the system actuating over a close-loop disregarding the reward. On the right is the re-estimated matrix that was obtained from Eq. 15 while the robot was exploring with the self-organised probing signal. In Fig. 9, the reward obtained by the left and middle matrices can be seen.

while in other cases the correlations values appear blurred, see the centre image in Fig. 4.

The third matrix is learned based on the reward (Eq. 16) while exploring using the homeokinetic adaptation rule. Correlations in one leg can be seen in the bottom graphic of Fig. 5, this behaviour has been learned within a small time of exploration and the rotational displacement of the leg can be seen in the blue line in Fig. 6. The contact in the ground is less and the exploited state space is smaller, although this still generates a behaviour that is positive towards reward.

The relationship between degrees of freedom from different legs is illustrated by Fig. 7, where we show the relation between a front leg with the lateral middle leg in the horizontal direction. The tripod gait generated by the CPG -the upper and middle graph of the figure- shows the expected phase relations. The same relation is observable in the learned matrix outlining an incipient tripod gait. This generation of the later behaviour is not influenced by the designed matrix which is shown here only for comparison.

The result of the longer experiment can be seen in Fig. 8 where the averaged reward of the tripod gait produced by a designed matrix, the homeokinetic controller, and the learned from reward matrix has been collected for 30 minutes of closed-loop exploitation. The reward of the CPG-style matrix is consistent and positive for all the experiment as expected. The homeokinetic reward is small and also consistent in time, since this controller is not promoted to follow any specific action other than explore coherently. The bigger amplitude of the reward in the learned approach is interpreted as the robot behaving with a bigger variety of actions that tends to maximise the reward but still not completely removing all the actions that leads to a negative reward behaviour. The relations shown in Figs. 5, 6 and 7 holds for some of the degrees of freedom but not for all of them. The final behaviour of the robot produces movement to the front and to the side as well. It can be seen that the homeokinetic

Figure 5: Considering a single leg controlled by a designed coupling matrix (top) we observe a phase shift between the horizontal (red continuous line) and vertical (green dashed line) actuation pattern. The movement of the leg (middle) does not follow the trajectory precisely, but keeps a similar phase shift. Using the present approach (bottom, Eq. 16) the movement pattern becomes more smooth which may point to a reduced energy consumption, but the phase shift has increased, the speed of the robot (as implied by the guidance matrix  $W^{r[+]}$  Eq. 15) being in the same range, see Fig. 8

exploration produces a small quantity of reward so the captured behaviours are an average of good but still not maximum rewarded actions. Note that the learned matrices have been normalised and multiplied by a factor in order to make the robot responsive in the closed-loop mode, this is required as the acquired results tend to be not big enough given the averaging nature of the approach.

## Discussion

We should note that the effect of the discovered structure may not always be beneficial for the robot by itself, but the potential misguidance can be diminished by a manipulation of the value function. As the shape of the robot's body distinguishes one of the directions of movement, there is also a bias in the exploration towards the forward direction. If the goal was instead to move backwards, then our algorithm would fail to provide a direct advantage, but the propagation of the opposite policy values of the policy may still provide a better starting point than random initialisation. Nevertheless, our results confirm that even if the exploration does not directly bring about a coherent behaviour that will receive high reward, it can still induce an acceleration of the learning of the task.

Obviously, also the learning scheme based on Eq. 15 will not be effective for all systems and that more complex relations between reward and sensorimotor coupling than studied here are clearly possible, but it is not the goal to im-

Figure 6: Configuration space representation of the trajectories from Fig. 5. The red continuous line represents the CPG-style matrix, the green dashed line is for the behaviour learned by following the first case without reward and the blue-dotted line represents the rotation learned by the system following Eq. 16.

pose these relations precisely, but rather to introduce a bias into the self-organising system such that any deviations between the true sensorimotor couplings and the relation that is implied by the guidance matrix  $W_{r^{[+]}}$  are resolved by the exploratory behaviour of the self-organising controller. We should remark, however, that a substantial deviation between guidance and realisable behavioural modes may compromise the efficiency although usually not the effectiveness of the control.

The use of the rectified reward signal in Eq. 15 avoids a critical step in the low-dimensional case that was considered in the first part. If the reward signal is negative, taking the opposite action might not always be beneficial or even possible. We have, thus implicitly assumed in the first part, that the opposite action is meaningful and in the second part that all positive rewards are actually relevant for the task which is not required in many other algorithms where only difference of reward signals enter.

## Conclusions

We have studied an exploratory self-organised mechanism for discovering promising initialisations for a parametrised policy and to establish coordination among the controllable degrees of freedom of a robot. We used a homeokinetic controller that is based on sensible and predictable exploration and does not require explicit knowledge of the robot's configuration or the environment. The approach is illustrated by a low and a high dimensional tasks implemented in a six-legged robot. The results imply that the initialisation of the parameters for the function approximation by a self-organised approach improves the learning of the proposed

Figure 7: In tripod gait, opposite legs follow an antiphase movement (red continuous line represents front-right leg and green dashed line represents middle-left leg horizontal position), which can be enforced by a designed matrix (top). A similar pattern is discovered by the system following the designed matrix (middle). For the present approach (bottom, Eq. 16) the movement pattern is similar but does not reproduce the same trajectory for all expected DoF as in the designed matrix.

tasks and that in high-dimensional set-up the correlation between degree of freedom can be acquired to improve the long-term reward.

## Abstract

The Ant Colony Optimization (ACO) meta-heuristic is a proven approach for solving complex distributed problems, being the routing problem one of such. By exploring the surroundings and indirect communication through pheromones, ants can find and follow the shortest path between a food source and its nest. Based on these characteristics, we present an ant-based algorithm for performing in-network resource search in a swarm-like Peer-to-Peer network. By marking connections that share same interests with a synthetic pheromone, a node can easily find a resource without having a significant impact on the network performance. Our approach focuses on decreasing the number of messages generated by each search, without having a negative impact on user experience. To achieve this, we present an algorithm that dynamically adapts based on the information a node has of its surroundings. The more information a node has of its neighbors, the higher the probability of choosing an exploitation strategy over an exploration one. Furthermore, the higher the number of nodes visited by an ant (and thus different paths followed), the lower the number of nodes explored in an exploration strategy. In order to decrease the number of messages sent to nodes that have already processed it, the parent ant informs each of its cloned ants about all the nodes to which each of these cloned ants will be sent to. Through simulation, we show the impact of these design choices in the algorithm's performance and discuss how it can be configured in order to adapt it to different networks.

## Introduction

Peer-to-Peer (P2P) protocols rely on decentralized architectures for providing a large number of services like VoIP, video streaming, file sharing, etc. This architecture allows P2P networks to be extremely scalable, since every node can connect and exchange resources with every other node (being storage, processing power, content, etc). Due to these characteristics, P2P protocols account for a high percentage of Internet traffic (Cisco, 2011)(Sandvine, 2011). One of the most popular architecture in P2P networks are swarms, where the resource sharing is done by grouping peers sharing a same resource in a swarm. These swarms are isolated from each other, and for a peer to share different resources, it has to participate in several different swarms. Due to this

swarm-like architecture, in-network search becomes difficult to implement. Although it is still possible to search for the resource identifier, in most cases, a peer needs to hold that resource in order to generate the identifier or search for it outside the network. This means that this identifier has to be either known at start or be generated with specific resource information that might not be known while performing a search. As for keywords search, these networks usually rely on outside services. However, there are several techniques that can be used to implement in-network search through keywords. Many of these techniques are nature-inspired algorithms that try to reproduce behaviors observed in nature. This work presents ASAP: an Ant Resource Search Algorithm for swarm-like P2P networks based on the Ant Colony Optimization (ACO) meta-heuristic (Dorigo and Caro, 1999)(Dorigo and Gambardella, 1997). By sending messages (ants) over the network and marking with a synthetic pheromone the links between nodes that lead us to a search response, we can forward future searches through those same links. By carefully choosing to whom the search messages should be forwarded to, we minimize the impact on network performance since flooding is avoided and less data is exchanged, resulting in lower bandwidth consumption in order to perform a search. As for user experience, it can also be improved since more and faster results can be achieved. Our approach focuses on dynamically adapting to the query results obtained. The algorithm was designed to evolve gradually from an exploration strategy, where a search is forwarded to many nodes in order to gather network information, to an exploitation strategy, where only the ones with the highest pheromone value receive and process the search message. However, the strategy choice also depends on the number of nodes already visited by the ant. If an ant knows that it or some clone already visited a high number of nodes, the possible number of paths the search is following increases and thus we can focus on forwarding the ant to the nodes that have a higher pheromone value. This way, we avoid flooding the network until the time-to-live (TTL) of the ant is reached. Furthermore, we also focus on minimizing the total number of messages sent between two

nodes that have already processed that same search. Discarding these messages has a significant impact on the network performance but none on the user experience.

Through simulation, we evaluate the algorithm's performance and show how the parameter configuration should be done based on some network properties. The simulated environment ran on peersim (Montresor and Jelasity, 2009) in a simulated swarm-like content sharing P2P network with a total number of 10000 nodes distributed over 50 different swarms, with each of the swarms sharing different content. As in real networks, nodes enter and leave the network throughout the experiment. Our results show the impact of the algorithm in both network performance and user experience. We show how the parameter configuration and variation affects the algorithm's performance and also show the importance and impact of some choices made during the development of the algorithm.

This paper is organized as follows: Section II gives a brief explanation on swarm-like P2P networks and Section III describes an overview of some of the related work done in this area. Then Section IV presents the algorithm, design and choices made during development, and Section V describes the simulation environment and obtained results. Finally, Section VI presents the final conclusions.

### Swarm-like P2P networks

Swarm-like P2P networks aggregate nodes that share the same resource in a swarm. These swarms are isolated and independent from each other, where the nodes that belong to it only share a single resource among themselves. However, nodes can participate in as many different swarms as they please, as long as they are willing to share different resources. These multiswarm nodes can operate as a bridge between different swarms, connecting the isolated swarms with each other. In these P2P networks, despite being aggregated into swarms, nodes are not necessarily connected to all others that participate in the same swarm. Figure 1 illustrates a swarm-like P2P network, where the lines represent the connection between two nodes.

Figure 1: Swarm-like P2P network architecture.

Although proving to be a successful architecture for resource sharing, these networks usually do not provide an in-network keyword search mechanism due to their characteristics. In a swarm-like P2P network, in order for a node

to make a specific in-network keyword search, it needs to send a message with the desired keyword to all or some of its neighbors, who will then forward it until a result is found or the nodes stop forwarding the message. One of the biggest problems with this approach is its impact on network performance as it can consume a great amount of the available bandwidth if the number of messages generated by each search is too high. On the other hand, if the number of messages is too low the search algorithm might have difficulty in finding resources that the node's closest neighbors don't have. In order for the algorithm to achieve best results, it needs to have as little impact on the network as possible and, at the same time still be able to find resources in the network. Furthermore, the search algorithm also needs to be able to adapt as nodes enter and leave the network. For this reason, in-network search is usually made through the resource identifier that, in most cases, is generated based on specific resource information that a node might not have if it does not hold that resource. As for keyword search, it is usually provided by services outside the network.

Figure 1 shows the message flow for a keyword search initiated by Node 1 in swarm A. The message is forwarded from swarm to swarm by the bridge nodes (the ones that participate in multiple swarms) until it reaches a node that has that resource, then a response message is sent back through the same path to Node 1.

### Related work

The Ant Colony Optimization (ACO) meta-heuristic has been adopted by many to address complex distributed problems like routing problems in computer networks. One such work is SemAnt (Michlmayr, 2006), an ant-based algorithm to provide a distributed search engine in an unstructured P2P content sharing network. In SemAnt, each peer holds a table with a pheromone value associated with a specific keyword and a node. These keywords are predefined for the whole network. When an ant finds a desired content, it generates a backward ant that will follow the same path backward and update each corresponding pheromone value. From time to time, there is an evaporation rule that decreases the pheromone values in the tables. Though simulation, the author shows how the SemAnt outperforms the k-random walker approach (Lv et al., 2002). However, the simulated environment was based on a static network. One other work that focused on using the ACO for search in unstructured P2P networks is ERAntBudget (Wu et al., 2008). This work combined the Budget mechanism (Gkantsidis et al., 2005) and the ACO principle in an attempt to avoid generating a large amount of network traffic when searching for popular content, since there is a high probability of a query returning too many results. One other objective was to improve the query hit ratio for unpopular objects. Though simulation they compare ERAntBudget with other used techniques and showed that it can achieve a higher success rate using

less bandwidth. Later, the same authors presented a modified version called AEAntBudget (Chen et al., 2010). This new version inherited the characteristics of ERAntBudget and also provided mechanisms for progressively expanding the search scope based on previous results. With this modification, AEAntBudget can achieve better results than ERAntBudget. AntSearch (Wu et al., 2006) also adopts an ACO technique for query flooding in a P2P network. However, the authors' focus is in identifying free-riders, peers that consume but do not share their resources with the network. To do so, AntSearch uses pheromone values to identify these free-riders and avoid sending messages to the same, generating a smaller number of messages and getting query hit from peers that have a higher probability of sharing their resources with others.

## Model

### ANT colony's foraging behavior

Every living organism shows a foraging behavior which can be defined as: (1) search for a food source, (2) catch the food source and (3) ingest food source. Although it can be defined by the previous three steps, every organism has adopted and developed its own way of performing each action, optimizing it as needed. A well-known example is the ant colony. Ants by themselves are animals that do not appear to have much of an intelligent behavior, however, when in colony, they show a remarkable intelligent behavior. Ants always follow the shortest path between their nest and a food source. When searching for a food source, ants drop small amounts of pheromones so others can follow. When a food source is found, ants drop a significant larger amount of pheromones. When other ants leave the nest, the paths with larger amounts of pheromone have higher probability of being chosen. However, pheromone evaporates over time which results in larger amounts of pheromones for the shortest paths, as they are traveled by more ants.

The study of this complex behavior has resulted in many intelligent algorithms that have been successfully used for resolving complex and time consuming problems. The Ant Algorithm has been used to solve many different problems. This work will focus on the usage of an ant algorithm for resource searching in swarm-like P2P networks. By marking desired links with a synthetic pheromone, message forwarding will be done through the shortest path with higher probability, and thus save network resources such as bandwidth. Peers processing power can also be saved by processing less undesirable messages.

### ASAP

Although P2P networks are based on decentralized architectures, many still depend on a centralized server for resource search within the network. Despite data exchange being done between nodes, resource search is done outside the network and depends on centralized services. The objective

of this work is to study how this dependency could be broken by implementing in-network resource search through an ANT algorithm for query routing. Based on the ant foraging behavior, a distributed search engine can be implemented inside a P2P network. By marking, with synthetic pheromones nodes and connections that share same interests, a node can easily find the resource it is looking for, without having significant impact on the network's performance.

In order for a node to persist the routing information, each node needs three tables:

1. A table with pheromone values for each category, for each node. Each node can have different resources or know others with same, similar or very different resources. For this reason it is important to differentiate the nodes based on the category of the resources.
2. A table with an association between each category and its strategy weight value. Each node needs different strategies for processing different category searches, depending on the amount of information it has already gathered from previous searches for that category.
3. A table with the TTL value for each category. In order to improve network performance, the TTL value can be different for each category based on the information gathered by previous searches.

When a node searches for a specific resource in the network, it creates a query with a keyword and its respective category. The keyword can be any sequence of characters. As for the categories, they are predefined for the whole network and cannot be changed for a single node. Every resource has to be assigned to a category, otherwise it cannot be found.

When a node receives a query message, it checks if it holds any resource for the searched category. If the node is sharing resources for that category and it matches the searched keyword, then the node sends a reply message back through the same path. The reply message is responsible for updating the routing tables for each node it visits on the way to the one that started the query. This information will then be used by future searches for message routing optimization.

The algorithm is divided into three stages:

1. State transition: When ants choose the path to follow. Depends on the amount of pheromone the path has and the number of resources the end node has.
2. Pheromone update: When an ant finds what it is looking for, it drops an amount of pheromone that depends on the cost of the path.
3. Pheromone evaporation: Over time, pheromone evaporates and decreases for each of the marked paths.

The first step, state transition, is defined by two strategies: (1) exploration, where the ant explores the surrounding nodes and (2) exploitation, where the ant exploits the

existing information collected by its predecessors. The exploitation strategy selects the node, to which the message is sent, by choosing the one that has the highest combination of both pheromone value and number of resources. As for the exploration strategy, instead of choosing only the one with the highest combination of both values, it selects a set of nodes which have not yet been visited by the ant and calculates the probability distribution for all of them, based on both pheromone and number of resources values. If their probability is above a pre-determined threshold, the ant is cloned and sent to each one of these nodes. In order to select one of the strategies, the node uses the following equation:

$$\begin{cases} \text{Exploration,} & \text{if } rand > w_c \\ \text{Exploitation,} & \text{if } rand \leq w_c \end{cases} \quad (1)$$

where  $rand \in [0, 1]$  is a random generated number and  $w_c \in [0.2, 0.8]$ , a threshold to define the probability of each strategy being chosen for category  $c$ . This parameter starts at its minimum value of 0.2 and is incremented each time there is an update to the pheromone tables for a given category, to a maximum value of 0.8. When there is a pheromone evaporation, this value is decremented. This forces the algorithm to use an exploration strategy during the startup phase and, as the node gathers more and more information about its surroundings, the exploitation strategy is preferred, in an attempt to increase network performance. Equation 2 shows how this value is modified, where  $\tau_{update}$  and  $\tau_{evaporate}$  are weight values that determine how much the  $w_c$  parameter should increment and decrement over time.

$$\begin{cases} w_c = \tau_{update} \cdot w_c, & \text{for pheromone update} \\ w_c = \tau_{evaporate} \cdot w_c, & \text{for pheromone evaporation} \end{cases} \quad (2)$$

After choosing the strategy, if exploitation, the ant chooses its next node  $s$  through Equation 3.

$$s = MAX_{u \in U \cap u \notin s(F_q)} \left( \tau_{cu} \frac{\gamma_u}{10} \right), \quad (3)$$

where  $U$  is the set of all known and active nodes,  $s(F_q)$  is the set of nodes already visited by this ant and others that it might know of,  $\tau_{cu}$  is the amount of pheromone for category  $c$  in node  $u$ ,  $\gamma_u$  represents the total number of different resources node  $u$  has.

If the choice was exploration, then the node chooses a set of neighbors to send the ant to, instead of sending just to the one with the highest pheromone concentration and highest number of resources. First, the node calculates the probability distribution for all neighbor nodes, through Equation 4.

$$p_j = \frac{\tau_{cu} \frac{\gamma_u}{10}}{\sum_{u \in U \cap u \notin s(F_q)} \tau_{cu} \frac{\gamma_u}{10}}, \quad (4)$$

then, with the number of nodes already visited by the ant, a percentile  $q$  is calculated using Equation 5.

$$q = \begin{cases} 1, & \text{if } \beta * Count(F_q) \geq 1 \\ \beta, & \text{if } \beta * Count(F_q) = 0 \\ \beta * Count(F_q), & \text{Otherwise} \end{cases} \quad (5)$$

where  $\beta$  is a constant, such that  $\beta > 0$  and  $Count(F_q)$  is the total number of nodes that have been visited by this ant and others that it might know of. After this, all the probability distribution values, calculated in Equation 4, are sorted in ascending order where the value  $k$  corresponds to the percentile  $q$  for that list of values. For every node  $j$  that satisfies the condition  $p_j \geq k$ , the ant forwards its clone to that node.

The exploration strategy will gradually evolve into an exploitation strategy as the ant visits more and more nodes, being  $\beta$  the value that defines the speed at which this happens. Furthermore, in an exploration strategy, when the ant clones itself it passes all its information to its clones, including the nodes that will be visited by each of its clones. For example, node A send two cloned ants to node B and node C. The cloned ant that reached node B will know that there was another ant that was sent to node C and thus will not send new ants to that node as it has already processed the query. These methods are mainly used for improving network performance, since it is expected to result in a lower number of messages sent and processed by each node. These methods decrease the number of messages between two nodes that have already processed the message, thus decreasing redundant cross-communication. For identifying a message as corresponding to an already processed one, each message is associated with a unique identifier and nodes keep a record of all the messages they already processed. This way, nodes discard messages that have already been processed. In both strategies, the total number of different resources, the neighbor node has, is also used to calculate if an ant should be forwarded to that same neighbor node. The nodes with a higher number of resources are more likely to have a resource a node is looking for. Furthermore, since they participate in multiple swarms, the query will be sent to a higher number of swarms, increasing the probability of finding an answer. This is also increasing the speed of convergence of the algorithm to find the shortest path.

A message is also associated with a time-to-live (TTL). This parameter is used so that the query does not continue endlessly. If the TTL is reached during a search, the ant stops and dies and no result is found. However, if the ant finds a result, it stops and goes back the same path. In swarm-like networks, where nodes are grouped into swarms that share the same resources, you only need to find one node to be able to join the swarm(s) that node is participating in. For this reason, the ant does not need to continue after finding a result. When returning after finding a result, the ant updates all the pheromone values for the searched category in each node it passes through. The pheromone value is updated as shown in Equation 6.

$$\begin{cases} \tau_{cu} = \tau_{cu} + Z, \\ Z = \gamma_q \frac{TTL_{max}}{2 \cdot h_{qr}} \end{cases} \quad (6)$$

The pheromone update equation depends on: the number of nodes visited by the ant from the response node to the current node ( $h_{qr}$ ), the maximum TTL for the ant ( $TTL_{max}$ ) and the value  $\gamma_q$  which represents the total number of swarms the response node participates in. This equation was designed to differentiate the responses to a query based on the total amount of different resources the response node holds as well as the number of nodes between origin and destination. This means that a path to a node that has a higher number of resources will have a higher increment in the pheromone values than another node that, despite also having the desired resource, has a lower number of resources. The pheromone increment is also higher for smaller size paths, that is paths with a lower number of nodes between origin and destination.

As for the pheromone evaporation, a global update rule was used. For every predefined interval  $T$ , each node applies the pheromone evaporation rule shown in Equation 7 for every row in its routing table. In this rule,  $\tau \in [0, 1]$ , is the amount of pheromone that should evaporate in this interval.

$$\eta_u = \eta_u \cdot (1 - \tau) \quad (7)$$

Many of the parameters used in the algorithm should be tuned based on network properties. For example, parameters such as  $TTL_{max}$  or  $\beta$  need to take into account the network size and average swarm size, so that the search does not have a negative impact on both network performance and user experience.

### Use case

In order to fully understand the algorithm's workflow, we present a use case scenario where a node participating in a P2P network queries for a given resource. Figure 2 represents the network for this use case, where the lines represent the connection between two nodes. There are three swarms: A, B and C. While there are some nodes that only participate in a single swarm, nodes B1 and C1 participate in two swarms and work as a bridge between swarms A and B and swarms B and C, respectively. Each of the swarms represents a different resource. Node A1 just joined the network and has no information on its neighbors.

In this scenario, Node A1 initiates a query for the resource being shared in swarm C by Nodes C1, C2 and C3. First, the algorithm calculates  $rand$  value and determines the usage of exploration and, since it has no information on its neighbors, it sends an ant to both Node A2 and A3. Since both ants know that they were sent to all of Node A1's neighbors, no messages are exchanged between Node A2 and A3, since they are already processing the search query. Node A2

Figure 2: Swarm-like P2P network for use case.

does not have the content and does not have any other neighbors so it discards the message. As for Node A3, it uses the exploitation strategy and forwards the ant to Node B1. After this Node determined the use of exploration strategy, it calculated the following probability distribution values for its neighbors: [B3 - 90 ; B2 - 103 ; B4 - 250]. Then it calculates the percentil  $q = 0.5$  that, when applied to the probability distribution values, results in  $k = 103$ . Since both Nodes B2 and B4 have a value equal or greater than  $k$ , the ant is forwarded to these nodes and not to Node B3. In Node B1, the ant only passed through one node thus the percentil  $q$  is low. However, if the ant had already passed through a high number of nodes, the percentil value would be much higher and the ant would only be sent to Node B4. After receiving the ants, Nodes B2 and B4 don't exchange messages between each other since each one knows that the other is already processing that same search, avoiding sending redundant messages. After receiving the ant, Node B4 forwards it to Node B5 which forwards the ant to Node C1. Node B2 also forwards the ant to Node C1. In this case, Node C1 can actually receive the query two times since Node B2 and Node B5 don't share the same parent ant so they cannot know that the other one also sent an ant to Node C1. Since Node C1 has the desired resource, the search ants are not forwarded anymore and a response ant is sent through both paths. The response ants will increase the pheromone values for every link they pass through, following the paths: (1) C1-B2-B1-A3-A1 and (2) C1-B5-B4-B1-A3-A1. Despite the pheromone increase in both paths, path (1) will have a higher increase than path (2) since the ant passes through a fewer number of nodes. The paths A1-A3 and A3-B1 will have their pheromone value increased twice since both responses pass through these paths. This pheromone value is only increased for the category to which the desired resource belongs to. Future queries initiated by Node A1, for a resource with that same category, will have a higher probability of following the previously discovered paths.

### Simulation and Results

The simulated environment consisted of a content sharing swarm-like network topology with a total number of 10000

nodes randomly distributed over 50 swarms, according to the values in Table 1. Each swarm had a minimum size of 200 nodes and each node was connected to at least 10 other nodes. Each swarm was also associated with a different keyword that identified the content being shared on that same swarm. Since swarms are independent and unrelated with each other, some nodes participated in multiple swarms, working as a bridge between the different swarms. Table 1 shows the number of nodes that participated in multiple swarms.

Number of swarms	1	2	3	4	5	6
Number of nodes	2000	4000	2500	700	500	300

Table 1: Number of nodes that participate in one or more different swarms.

The experiment ran on a dynamic network, where a random number of nodes entered and left the network at any given time. However, no more than 5% of the network size (in this case, 500 nodes) could leave the network at the same time. Whenever the nodes reentered the network, they joined the same swarms they were previously participating in, since the node already had or was interested in those resources. However, the node established new connections different than the previous ones. The pheromone tables and other dynamic parameters, such as the strategy weight value were also set to default values upon reentering the network. As for the categories, we defined five: movie, music, application, tv show and book. During the experiment, 12000 queries were made.

Table 2 shows the initial parameter values. Since  $\beta$  defines the speed at which the algorithm evolves an ongoing search from an exploration strategy to an exploitation strategy, we varied this parameter in order to show how important its correct configuration is for the algorithm to achieve best performance.

Parameter	Value
Initial weight strategy for each category ( $w_c$ )	0.2
Weight strategy update ( $\tau_{update}$ )	1.25
Weight strategy evaporate ( $\tau_{evaporate}$ )	0.85
Initial pheromone value ( $\tau_{cu}$ )	0.009
Pheromone evaporation ( $\tau$ )	0.03
TTL	24
$\beta$	1; 0.1; 0.01; 0.006

Table 2: Algorithm parameters value.

As explained in Section IV-B, the strategy weight value

changed throughout the experiment, from a minimum value of 0.2 to a maximum value of 0.8. This allows a node to explore with higher probability its surroundings during the startup phase, when it enters the network and has no information whatsoever. This will lead to a higher number of messages exchanged during the startup phase. However, as the node gathers information about its neighbors, the preferred strategy changes to exploitation, which in turn will reduce the number of exchanged messages, as well as the paths an ant follows that do not lead to an answer, thus improving network performance. Figures 3 and 4 show this behavior.

Figure 3: Number of messages generated by each query, with  $\beta = 0.01$ .

Figure 4: Number of paths that do not lead to an answer per query, with  $\beta = 0.01$ .

The first experiment ran with a  $\beta$  value of 0.01 and the algorithm's performance was compared to two modified versions of it, in order to show the importance of two choices made during the algorithm's development. In the first modified version (No parent memory), we modified the way the

cloned ant keeps the memory from its parent ant. When an ant cloned itself, it did not pass to its clone the information referring to all the node's neighbors that it would also be sent to. This way, an ant only knows the nodes that it visited and not the nodes visited by its first clones. As for the second modified version (No number of resources), the parameters  $\frac{\gamma_u}{10}$  (the total number of different resources node  $u$  has) were removed from the algorithm. This way, the exploration/exploitation strategy equations were modified to only take into account the pheromone value. The first measurement made was the average number of messages processed by each node. Table 3 shows the results.

Number of swarms node participates in	Original	No number of resources	No parent memory
One	49,56	1119,17	3212,34
Two	224,05	1750,16	6253,71
Three	1365,15	2603,32	9132,34
Four	3438,31	3636,62	12959,42
Five	6625,93	4875,91	17700,18
Six	11272,8	6398,05	23340,49

Table 3: Average number of messages processed by each node that participates in one or more swarms.

Network performance is achieved by reducing the number of messages generated by each search to a minimum value so that a resource is still discovered. Table 3 shows just that. By passing to the cloned ant the information about all the node's neighbor the other cloned ants are also going to be sent to, the ant has more information about which nodes have already processed the search, avoiding visiting again these nodes. This way, the number of messages in the network decreases without affecting the search algorithm performance. As for the removal of the  $\frac{\gamma_u}{10}$  parameter, it allows the algorithm to explore more the nodes with a fewer number of resources, thus distributing the workload more evenly in the network. However, the nodes with more resources are the ones that have a higher number of connections and have the highest probability of holding a resource or knowing someone that holds a resource that is desired. Although the usage of this parameter might have an impact on the network performance, as it does not distribute the workload evenly, it increases the probability of a node finding a resource in the network. Figure 5 shows the importance of the memory passing mechanism and differentiating nodes based on the number of different swarms they participate in, and how it can affect user experience when searching for resources in the network.

Both Table 3 and Figure 5 also show the tradeoff there needs to be between network performance and search performance. When distributing more evenly the workload in the network, we also decrement the number of queries that find

Figure 5: Cumulative distribution function for the queries with a hit.

at least one result. When focusing the workload in the nodes that have a higher probability of having a resource, we increment the number of queries that find the search resource, at the expense of network performance. Figure 5 also shows an unexpected behavior. When removing the memory mechanism, the algorithm generates a much higher number of messages (Table 3), however it achieves a lower hit rate than the original version. This can be explained by the large number of generated messages that are sent to nodes that have already processed the message, and thus are discarded.

After showing the importance of these algorithm's behaviors, we ran the simulation with four different  $\beta$  values: 1, 0.1, 0.01 and 0.006<sup>1</sup>. The  $\beta$  parameter defines how the exploration strategy evolves into an exploitation one, having direct impact on both network and algorithm performance. First, we compared how this value affects both the distribution of the workload in the network and the average number of messages generated by each search. Table 4 shows the results.

Number of swarms node participates in	$\beta$			
	1	0.1	0.01	0.006
One	1,63	29,29	49,56	78,76
Two	1,88	51,2	224,05	720,54
Three	2,25	64,67	1365,15	3853,47
Four	2,7	96,32	3438,31	7322,91
Five	63,25	656,66	6625,93	11798,08
Six	781,49	4954,7	11272,8	16987,04

Table 4: Average number of messages processed by each node that participates in one or more swarms.

As expected, by increasing the  $\beta$  value, the exploration strategy evolves more rapidly into an exploitation strategy,

<sup>1</sup> Simulator limitations forced the lowest value to be 0.006

generating a lower number of messages and focusing most of these messages in the nodes with the higher number of resources. As the value decreases, the algorithm makes a larger use of the exploration strategy, thus generating more messages and exploring more the nodes with a lower number of resources. This exploration strategy is very important in gathering information from the surrounding network so that more paths can be explored and the desired resource found. This has a direct impact on the search results and consequently the algorithm's performance. However, having a  $\beta$  value too low will result in a network flooding and consequently have a negative impact on network performance. Figure 6 shows a CDF with the percentage of queries that find the searched resource.

Figure 6: CDF for the queries with a hit, with different values for the  $\beta$  parameter.

In order to configure the  $\beta$  parameter, the average swarm size in the network and the percentage of nodes that actually participate in multiple swarms need to be taken into account. If a network has a low percentage of multi-swarm nodes, the  $\beta$  value should be low enough so that the algorithm does not focus all its messages on these nodes and distributes its load throughout all other nodes. This behavior can be observed in Table 6 for  $\beta = 1$ . On the other hand, if the network has a high percentage of multi-swarm nodes, the  $\beta$  value should be high enough so that it does not flood the network with query messages. The  $\beta$  parameter can have a significant impact, either positive or negative, on network and algorithm performance and thus should be configured accordingly to each network it is used in.

## Conclusions

This work presents an ant-based algorithm capable of providing a search mechanism inside swarm-like P2P networks. The algorithm focuses on minimizing the impact it has on network performance without affecting the user experience. This is done through pheromone marking, strategy and message forwarding adaptation, based on the total number of

nodes already visited by the search ant. This way, the number of messages generated by each search query decreases as the node has more information about the surrounding network. Our simulations show how the algorithm behaves and reacts to different parameter configuration and how it can be configured to achieve best network performance and results. The simulation results also show the reason for some design and development choices made upon creation.

## Abstract

We simulate the swarming behavior of three synthetic animal species that differ only by the degree of perception they have on their fellow animals. The species are called *mosquitoes*, *birds* and *fish*. The swarms that comprise many individuals of each species in turn move randomly in a rugged potential landscape. The *mosquitoes* pay no heed to one another. The *birds* follow a bunch of their nearest neighbours in front, based on strictly limited visibility. The *fish*, in turn, sense also far-away neighbors through their lateral line, as modeled by an exponentially decaying perception function. The simulations show that such local differences in perception by swarming individuals have global macroscopic consequences to the geometry of the corresponding swarms. These consequences are of persistent nature across many simulations with each species.

## Introduction

Humans, like many other animal species, are social. We are fundamentally geared to living in a herd of some 20 - 100 individuals, from our nearest primate cousins to decide. Many other animal species have much more intense social lives, with flocks extending to thousands of individuals. Large flocks - or swarms - have their own requirements as to the means of imposing collective social control over the individuals involved. The process of social co-ordination is bi-directional: on the one hand, swarm dynamics exerts control over each individual. On the other, swarm dynamics is a direct consequence of the collective motion of all of its individuals.

In this article, we compare the consequences on collective dynamics of different degrees and forms of perception of swarming animals through computer simulations. Many studies indicate that the bi-directional flow of information described above has an important defining role in determining the nature of swarm dynamics. The impact of information flow boils down to the question of how do the individuals in a swarm perceive the collective dynamics of the swarm - and to the reciprocal question of how does the reaction of individuals influence the collective dynamics of the swarm.

We shall study this question with computer simulations of the collective motion of swarms of three different types

of animals, all capable of moving in two spatial dimensions. These synthetic species are labeled as *mosquitoes*, *birds* and *fish*. They are set to move in a similar synthetic world with some external forces and constraints. But the way they perceive their fellow passengers is different, which has a fundamental impact on the nature of the corresponding collective motion of the swarm.

## Swarm dynamics with a difference

Collective swarm dynamics can be described in many ways, such as using ordinary or partial, deterministic or stochastic, differential equations. Classical models of *Eulerian type* (e.g., see Milewski and Yang (2008), Murray (2002), Mogilner and Edelstein-Keshet (1999) and Nagai and M. (1983)) are based on the **diffusion-advection-reaction** equation, governing the spatio-temporal dynamics of the population density:

$$\frac{\partial f}{\partial t} = \frac{\partial}{\partial x} \left( D(f) \frac{\partial f}{\partial x} \right) - \frac{\partial}{\partial x} (V(f)f) + B(f), \quad (1)$$

where the first term on the right-hand side introduces a Brownian motion with diffusion coefficient  $D(f)$ , the second term stands for advection with density-dependent velocity  $V(f)$  and the last reaction term may include birth or death processes.

Convection term results in attraction and repulsion effects, reflecting forms of social interaction between population members which implies that the direction and speed of motion of a particular individual is determined by the population density of the surrounding environment. One advantage of continuous models is the diversity of readily available analytic tools that facilitate their study.

Since the sensory systems of animals are limited, it is typically assumed that interactions have finite spatial influence. In most PDE-based models advection velocity is specified as a convolution (Mogilner and Edelstein-Keshet (1999), Edelstein-Keshet et al. (1997)):

$$V(f) = \mathbf{K} * f = \int_R \mathbf{K}(x - x') f(x', t) dx', \quad (2)$$

where the kernel  $K$  relates to the strength of animal-animal interaction per unit density with a distance  $x - x'$  between two sites, see Mogilner and Edelstein-Keshet (1999).

Another common approach is based on modeling the movement of each individual member of the total population comprising  $N$  identical members. In this so-called *Lagrangian approach* each individual member follows simple rules of motion, specified by either a system of stochastic differential equations, as was done in Burger et al. (2007), Morale et al. (2005), or via a hierarchical algorithm with a probabilistic decision-making mechanism, see Gueron et al. (1996).

In our simulations of synthetic animal swarms, swarming *mosquitoes* do not affect each other. The main factor that determines their motion is sensing features of a potential prey or heat source. Host-seeking behavior of mosquitoes was thoroughly considered in Cummins et al. (2012). *Mosquitoes* were treated as a number of independent agents, sampling concentration of attractive odor emitted from host individuals via mechanism of *klinotaxis*. The concentration is given by the convection-diffusion equation. In the present study, the *mosquito* case is modeled with a similar approach, but by different means.

In order to focus our study on the influence of perception on collective dynamics, we use an identical environment for all the swarms. This environment consists of a two-dimensional landscape that resides at the bottom of a "potential bowl" that describes the local habitat of the swarm. The swarm is therefore confined to a limited, but boundaryless, area. Inside the potential bowl, there are four obstacles at the corners of a square that repel individuals and cause the swarm to turn away from them. These obstacles can represent e.g. trees, buildings, rocks or repellents.

The dynamics of a swarm are directed both by external forces - such as the potential bowl above that forms a basin of attraction, and the obstacles that each constitute a repulsive force - and by internal forces created by the autonomous dynamics generated by the members of the swarm through their interaction. Both external and internal forces are represented in population dynamics as force potentials that are mediated by perception. In our model, we assume the external forces to be constant in time and independent of swarm dynamics, so as to focus on the autonomous dynamics of the swarm. In the real world, both external and internal forces are very much dynamic, as can be seen e.g. from any movie of dolphins chasing a school of fish.

Our autonomous swarm dynamics are broadly following a class of stochastic differential equation models introduced by Capasso and Morale in Morale et al. (2005) and Burger et al. (2007). In this kind of dynamics, there is a long-range herding force that keeps the swarm together, and a short-range repulsion force that prevents individuals from colliding.

Our three fundamental species differ only in the way that

Figure 1: General layout: global attractive potential in the center and four local sources of repulsion.

they can perceive their fellow animals. All the three species are only synthetic forms of life, but they are each given a familiar name that links each synthetic species to a related animal species.

- *Mosquitoes* do not perceive their fellow mosquitoes. Instead they move in Brownian motion, weighted by the gradient of the external potential field alone.
- *Birds* do see their fellow birds, but only up to a fixed distance limit in their front.
- *Fish* may see only their immediate neighbors, but because of their special pressure sensing organ, the lateral line, they can feel the movement of the swarm beyond their range of visibility. In this case, their perception function is a radial, exponentially decaying function.

### Basic dynamic equations

We consider the general layout for the three above-mentioned cases, see Figure (1), where a source of global attractive potential is located at the center of the experimental habitat of the species, and four short-term repulsive potentials are placed separately from one another. In the case of a *mosquito* swarm, we treat this setting as an indoor space amended with four sources of repellent and one intensive heat source at the center. In the two other cases, the layout can be treated as a domain inhabited with a population of animals which contains four obstacles, such as trees or rocks.

#### Mosquito swarm

The first case examines collective behavior of *mosquitoes* in presence of an intensive heat source and four patches covered with repellent (e.g., spray), modeled as a system of non-interacting particles driven by an external potential.

The heat source at  $\mathbf{x}^h$  is modeled as a Gaussian hump:

$$C_a(\mathbf{x}) = \exp \left[ -\frac{d^2(\mathbf{x}, \mathbf{x}^h)}{2\sigma_a^2} \right], \quad (3)$$

where  $d(\mathbf{x}^h, \mathbf{x})$  is the distance between point  $\mathbf{x}$  and the position of the source  $\mathbf{x}^h$ . The standard deviation of the Gaussian  $\sigma_a$  conditions the minimal distance at which the *mosquito* is able to sense the heat.

We assume that each *mosquito* is driven towards the source by the mechanism of **klinotaxis**, as it was conjectured in Vickers (2000) for the case of host-seeking behavior of real mosquitoes. During klinotaxis, an animal samples the concentration of attractive substance at one location, then changes location and repeats sampling, using its memory of the concentration to choose its next position Cardé (1996).

In the present study, the klinotaxis mechanism is modeled by employing a random walk. The **Metropolis algorithm** was introduced in the 1950s in statistical physics literature as a tool to sample probability distributions, see Metropolis et al. (1953). The Metropolis algorithm is based on an **accept-reject** step. Assume that we take a step from point  $\mathbf{x}^{n-1}$  to a candidate position  $\mathbf{x}^n$ . If corresponding probabilities are  $p_{n-1}, p_n$ , we accept the new position with probability

$$\alpha_a = \min\left(1, \frac{p_n}{p_{n-1}}\right) \quad (4)$$

Hence, the upward steps ( $p_n > p_{n-1}$ ) are always accepted, while steps downwards are accepted with probability  $p_n/p_{n-1}$ . Probabilities  $p_n, p_{n-1}$  are taken from a **proposal distribution**. Applying the above-specified sampling rule with adequate proposal distribution implies that the samples converge towards the underlying target distribution.

In our simulations random walk is employed as a proposal distribution. Consider a *mosquito* at position  $\mathbf{x}_{n-1}$  at iteration  $n - 1$ . It randomly selects a candidate position  $\mathbf{x}^n$  by

$$\mathbf{x}^n = \mathbf{x}^{n-1} + d\mathbf{W}, \quad d\mathbf{W} \sim N(0, \Sigma), \quad (5)$$

where the two-dimensional Gaussian  $N(0, \Sigma)$  conditions the step length for the random walk. The probabilities are associated with the distribution of heat, and may be given as an exponential of the heat concentration:  $p_n = \exp(-C_a(\mathbf{x}^n)/2\sigma_a^2)$ . The accept/reject probability can then be written as follows:

$$\alpha_a = \min\left(1, \frac{p_n}{p_{n-1}}\right) = \min\left(1, \exp\left[-(C_a(\mathbf{x}^{n-1}) - C_a(\mathbf{x}^n))/2\sigma^2\right]\right), \quad (6)$$

where  $\sigma$  is a scale which governs the probability of a step away from the source to get accepted: the smaller is  $\sigma$ , the less likely they are to get accepted. Our *mosquito* 'sampler' is eventually supposed to roam in proximity to the heat source.

Repellent is treated as Heaviside step function which stands for a **probability of rejection** for candidate position  $\mathbf{x}$ :

$$\alpha_r(\mathbf{x}, \mathbf{x}^r) = \begin{cases} 1, & \min_{j \in 1, \dots, N_r} d(\mathbf{x}, \mathbf{x}^r) \leq L \\ 0, & \min_{j \in 1, \dots, N_r} d(\mathbf{x}, \mathbf{x}^r) > L \end{cases}, \quad (7)$$

where  $d(\mathbf{x}, \mathbf{x}^r)$  is a distance from position  $\mathbf{x}$  to the source of repellent,  $L$  determines the range of coverage. One way to combine multiple repellents is to sum rates of rejection over all sources of protection and take Metropolis-type of probability:

$$\alpha_r(\mathbf{x}^n) = \min\left(1, \sum_{i=1}^{N_r} \alpha_r(\mathbf{x}, \mathbf{x}_i^r)\right), \quad (8)$$

where  $N_r$  is a total number of repellents. A *mosquito* swarm is represented as a number of individuals placed initially at random spatial positions on a rectangular patch  $[x_{min}, x_{max}] \times [y_{min}, y_{max}]$ . After that, every *mosquito* with initial position  $\mathbf{x}^0$  changes its location in accordance with the following algorithm:

#### Algorithm for swarm dynamics

1. Select a candidate position  $\mathbf{x}^n$  by adding Brownian increment to previous point, that is compute  $\mathbf{x}^n$  by formula (5).
2. Measure concentration of heat at new position as it was specified in formula (3)
3. Compute **probability of acceptance** for position  $\mathbf{x}^n$ :

$$\alpha_a(\mathbf{x}^{n-1}, \mathbf{x}^n) = \min\left(1, \exp\left[-(C_a(\mathbf{x}^{n-1}) - C_a(\mathbf{x}^n))/2\sigma^2\right]\right), \quad (9)$$

4. Compute **probability of rejection** by formula (8)
5. Generate a random number  $r \sim U[0, 1]$ ; if  $r < \alpha_a(1 - \alpha_r)$ , accept the new position  $\mathbf{x}^n$ . Otherwise, remain at the old position:  $\mathbf{x}^n = \mathbf{x}^{n-1}$ ;
6. Move to step 1,  $n \rightarrow n + 1$ .

#### Flocks of birds

Our second type of swarming behavior also features dynamics under a global attractive potential. It can be viewed as a population moving inside a wide domain of habitation. This domain includes several areas covered with obstacles that are avoided by population members. External attraction and repulsion is treated as in the previous case of *mosquito* swarming behavior.

In contrast to *mosquitoes*, this second type of animals is supposed to coordinate with fellow-individuals, i.e. exhibit a tendency to aggregate but to avoid over-crowding. In our present simulations, both interactive effects are introduced by means of **Kalman dynamics**, a term derived from the statistical data assimilation method known as **The Kalman Filter**, see Kalman (1960), Evensen (2003).

The Kalman filter produces a **state estimate** of a dynamic system as a weighted average of a **prior state** or predicted state, and of a **state observation**.

Suppose that at the step  $n - 1$  *birds* have occupied positions

$$\mathbf{x}^{n-1} = (\mathbf{x}_1^{n-1}, \mathbf{x}_2^{n-1}, \dots, \mathbf{x}_N^{n-1}), \quad (10)$$

where  $N$  is the number of *birds*. Firstly, **prior candidate positions**  $\mathbf{x}_i^n = \mathbf{x}_i^{n-1} + \mathbf{dW}$ ,  $i = 1, \dots, N$  are randomly selected and independent of one another. After that, every prior candidate point  $\mathbf{x}_i^n$ ,  $i = 1, \dots, N$  is amended with an observational increment:

$$\bar{\mathbf{x}}_i^n = \mathbf{x}_i^n + G_a (\mathbf{y}_i^a - \mathbf{x}_i^n) \quad (11)$$

to introduce cohesion towards closest individuals, which is a typical way of attaining synchronization between animals, such as schooling fishes and flocking birds.

In the current case, we assume that a long-range attraction rule applies to the nearest five neighbors of each individual, as has been observed in the case of real birds. Positions of viewed fellow *birds* are combined into an artificial state observation

$$\mathbf{y}_i^a = \frac{1}{N_o} \sum_{j=j_1}^{j_{N_o}} \mathbf{x}_j^n, \quad (12)$$

where  $j_1, \dots, j_{N_o}$  are indices of  $N_o$  closest neighbors to the side and ahead of the agent  $\mathbf{x}_i^n$ .

The **Kalman Gain**  $G_a$  can be adjusted to achieve a particular strength of cohesion: increasing  $G_a$  implies enhancement of aggregative behavior.

Short-range repulsion between *birds* can be modeled similarly:

$$\bar{\mathbf{x}}_i^n = \mathbf{x}_i^n - G_r (\mathbf{y}_i^r - \mathbf{x}_i^n), \quad (13)$$

where observation  $\mathbf{y}$  is composed as an average over the set  $\mathcal{N}_r = \{j | d(\mathbf{x}_i^n, \mathbf{x}_j^n) < d_{\min}\}$  of all positions located closer than at minimum distance  $d_{\min}$ :

$$\mathbf{y}_i^r = \frac{1}{|\mathcal{N}_r|} \sum_{j \in \mathcal{N}_r} \mathbf{x}_j^n. \quad (14)$$

Analogously to the above-described case of cohesion, the Kalman gain  $G_r$  in formula (13) governs the strength of repulsive interaction.

**Algorithm for collective dynamics** is applied to each individual agent  $i = 1, \dots, N$  separately

1. Select a candidate position randomly:

$$\mathbf{x}_i^n = \mathbf{x}_i^{n-1} + \mathbf{dW}, \mathbf{dW} \sim N(0, \Sigma). \quad (15)$$

2. Compute **probability of acceptance** for position  $\mathbf{x}_i^n$ :

$$\alpha_a = \min \left( 1, e^{-\frac{(C_a(\mathbf{x}_i^{n-1}) - C_a(\mathbf{x}_i^n))^2}{2\sigma^2}} \right) \quad (16)$$

3. Compute **probability of rejection** for position  $\mathbf{x}_i^n$ :

$$\alpha_r = \begin{cases} 1, & \min_{j \in 1, \dots, N_r} d(\mathbf{x}_i^n, \mathbf{x}_j^r) \leq L \\ 0, & \min_{j \in 1, \dots, N_r} d(\mathbf{x}_i^n, \mathbf{x}_j^r) > L \end{cases}, \quad (17)$$

where  $d(\mathbf{x}_i^n, \mathbf{x}_j^r)$  is a distance between the  $i$ -th agent and the center of  $j$ -th obstruct patch,  $L$  stands for the width of the patch,

4. Accept new position  $\mathbf{x}_i^n$  with probability  $\alpha_a(1 - \alpha_r)$ , in case of rejection, stay at the old position  $\mathbf{x}_i^n = \mathbf{x}_i^{n-1}$ ,
5. Apply Kalman dynamics to induce interactive behavior (cohesion and repulsion):

$$\begin{aligned} \bar{\mathbf{x}}_i^n &= \mathbf{x}_i^n + G_a (\mathbf{y}_i^a - \mathbf{x}_i^n) \\ &\quad - G_r (\mathbf{y}_i^r - \mathbf{x}_i^n), \end{aligned} \quad (18)$$

where observations  $\mathbf{y}_i^r$  and  $\mathbf{y}_i^a$  are computed by formulas (12) and (14), correspondingly;

6. Compute probability of rejection  $\alpha'_r$  for position  $\bar{\mathbf{x}}_i^n$  by formula specified in the item 3, accept position ( $\mathbf{x}_i^n = \bar{\mathbf{x}}_i^n$ ) with probability  $1 - \alpha'_r$ , otherwise, remain at the old position  $\mathbf{x}_i^n$ ,
7. Move to step 1,  $n \rightarrow n + 1$ .

### Schools of fish

Schooling behavior is modeled similarly to the previous case, except for the observation stage for cohesion. *Fish* are characterized by their ability to sense their fellow kin even beyond a certain range, which is reflected in the perception function applied at the state observation step as follows:

$$\mathbf{y}_i^n = \sum_{\substack{j=1 \\ j \neq i}}^N \exp[-\lambda d(\mathbf{x}_i^n, \mathbf{x}_j^n)] \mathbf{x}_j^n, \quad (19)$$

where observation weights decay exponentially with distance.

### Results

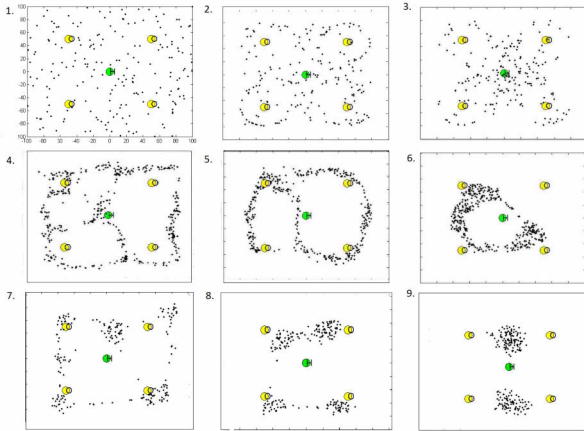

As to the pun in the title of the article - *mosquitoes* do not recognize any friends. *Mosquitoes*, by their definition as Markovian synthetic animals without regard for their fellow kin, keep happily flying on top of one another. It is lucky that they can be regarded as point-like particles in simulations!

The results of the simulations for all three species are illustrated in Figure 2. The three rows of the figure represent the three species. The columns from left to right represent an early state, one or two intermediate states, and a late state of the swarm, respectively, in each case. The upper-most left figure represents the common random initial state of all

Table 1: Values of model coefficients employed in experimental runs.

parameters	values
$\sigma_a$	1000
$L$	4
$G_a$	0.7
$G_r$	0.9
$\lambda$	1
$\sigma$	$1e - 3$

The final distribution of *birds* ,7.-8. Intermediate distributions of *fish* , 9. The final distribution of *fish*

three swarms. From these figures, we conclude that the answer to the pun is not the same for *birds* and *fish* as it is for *mosquitoes*. The former two species both react to their fellow flyers or swimmers, in a manner that has a fundamental impact on the geometry of the swarms they form. Despite the slightly different forms of the algorithms used for *mosquitoes* and for the other two "species" of synthetic creatures, their swarms start out similar. The disregard for fellow *mosquitoes* causes them to get distributed according to the geometry of the landscape, but concentrating on the level contours of their potential well. Only in late stages of the simulation do *mosquitoes* finally find their way to the bottom of their potential bowl.

*Birds*, on the other hand, are so attached to their fellow fliers that this property actually prevents them from reaching the bottom of the potential bowl. Instead, they circulate in a simply or multiply connected chain to the foreseeable future. This is caused by the attractive potential of the nearest *birds* that inexorably pull the *birds* away from their preferred feeding ground, because of the "horror vacui" that surrounds

it.

Finally, *fish* display yet another variety of swarm dynamics, since they can sense the presence of also far-away fellow swimmers. This property allows them to cluster into groups, instead of a continuous chain. In our rugged landscape, the end result is not a single cluster, but two clusters of *fish*, held away from each other and from the best feeding ground by the balance of mutual repulsion that would strengthen if the two schools would move closer to one another.

In all three cases, the final distributions of the swarms, flocks and schools are quite stable over many cycles of simulations. They therefore demonstrate clearly the macroscopic geometric consequences of the local degree of perception attributed to each synthetic species.

Increasing Kalman gain  $G_a$  induces clustering behavior in the swarm, hence the latter parameter should be kept sufficiently big to stimulate cohesion, but not exceedingly large, since it annihilates the motion caused by an external potential. To avoid this effect, Kalman gain which governs the attraction should be smaller than matching repulsion coefficient  $G_r$ , see Table (1).

## Discussion

We have demonstrated that under similar but non-homogeneous geometric circumstances, the degree of local perception by swarming animals has global geometric consequences for their corresponding swarm dynamics. Instead of behaving in a totally random or chaotic fashion, the swarms adopt persistent geometric shapes that are a function of the degree of local perception possessed by the individuals in the swarm, even as the individuals generally move in a similar stochastic manner. We have demonstrated three such geometries in the case of three synthetic species that behave like mosquitoes, birds and fish, respectively.

This empirical result is not very surprising, in view of corresponding results in deterministic differential geometry. In differential geometry, the difference between the dimensions of the kernel and co-kernel and of a local linear curvature operator, such as the Laplacian, determines uniquely the Euler characteristic of the manifold, as is stated by the Atiyah-Singer Index Theorem and its many analogues and generalizations. The Euler characteristic describes the difference between the number of edges and the number of vertices of an arbitrary triangulation, or simplicial complexification in dimensions higher than two, of the corresponding manifold and it is a topological invariant. This means that the Euler characteristic remains the same, no matter how the triangulation or simplicial complex have been constructed. It is, in particular, independent of the length of the edges in such a triangulation, and hence on its spatial resolution.

On the other hand, there are well-known analogies between curvature operators and random walks, such as the bijective relationship between Brownian motion and the

Laplacian. It is not trivial to extend such results, that depend crucially on the linearity of the curvature operator, to the non-linear stochastic dynamics discussed in the current paper. But the persistence of the limit geometry of the swarms observed in our numerical experiments seems to indicate that the bridge of analogies from random walks through corresponding differential dynamics onto the global topology of the limit swarm on a non-trivially connected manifold is a continuous path. But the fact that the resulting topology is different for different perception operators testifies to the non-trivial nature of these analogies: the topology of the swarm is not uniquely determined by the topology of the underlying spatial manifold, but also depends on the non-linear perception operator associated with the swarm dynamics.

# Some Remarks on Dynamics of Binary Chromosomes Population

Zbigniew Pliszka<sup>1</sup>, Olgierd Unold<sup>2</sup>

<sup>1</sup>Wroclaw Public Library, Sztabowa 95, 53-310 Wroclaw, Poland

<sup>2</sup>Wroclaw University of Technology, Wyb. Wyspianskiego 25, 50-370 Wroclaw, Poland  
olgierd.unold@pwr.wroc.pl

Population is the fundamental basis of any evolution (Novak, 2006). This statement is true both in biological and artificial evolutionary systems. Population dynamics studies short and long-term changes of the certain population features, and is a branch of life sciences. Here, we discuss new properties of population of binary chromosomes evolved by genetic algorithm (GA), which is one of the possible implementations of artificial evolutionary systems. In particular, we introduce a theorem (Theorem 3) allowing us to determine the minimal number of simple operations necessary to restore the entire space to explore. The work is partly based on Pliszka and Unold (2011, 2012).

The discipline of GAs (and broadly Evolutionary Computation EC) is still focused more on the empirical aspects of algorithms than theoretical studies. Methods, which are currently in use in theoretical studies of these algorithms, could be classified into one of the following groups: schema theory, Markov chains theory, dimensional analysis, order statistics, quantitative genetics, orthogonal functions analysis, quadratical dynamical systems, and statistical physics. Simplistic assumptions have frequently been adopted in the theoretical analyses and these have deformed the analyzed algorithms in such a way that they question the real connection between the results obtained and the investigated algorithms.

The essential step in GA/EC is to determine the representation of computational population (Hu and Banzhaf, 2010). Another one is to define the method of gene duplication. Most of GAs use linear binary representations, and the most standard one is an array of bits. Due to fixed size of such representations, their parts are easily aligned. This facilitates simple crossover operation.

In our approach binary chromosomes are represented as binary, fixed-length chromosomes, using an alternative to zero-one decoding technique, called Hadamard representation. The search space  $\{0, 1\}^n$  was replaced by  $\{-1, 1\}^n$ . Thanks to use a new binary model the requirement of orthogonal columns pairs is omitted. Subject of this study is the following set:

$$\begin{aligned} H^n &= \{(h_{s,n}, h_{s,n-1}, \dots, h_{s,2}, h_{s,1}) : \\ &\forall s \in \{0, 1, \dots, 2^n - 1\} \\ &\forall i \in \{1, 2, \dots, n\} \\ &h_{s,i} \in \{-1, 1\}\} \end{aligned}$$

Its elements represent all possible binary chromosomes of equal length  $n$ , where  $n$  is a natural number higher than 1. Note that the Hadamard representation is in fact a transformed Hamming space. The proposed representation has one, apparently insignificant property, which distinguishes it from the binary representation: a square of each coordinates is equalled 1. This fact draws two subsequent conclusions: the sum of the squares of coordinate of each element of the  $H^n$  space is constant and equals this space dimension, and there is no element with zero coordinates. The collection of these simple facts allows for the formulation of rules for phenotypes (indices) and development of automate methods of moving frame  $H^n$ , as well as determination of the distance (level of differentiation) between the elements of this space (Pliszka and Unold, 2011).

The use of Hadamard representation allows us to give theoretical proof for epistatic properties as well as exploration possibilities of a crossover operator. We say that the population is ancestral, if all its elements can be obtained from a primary (initial) population as a result of the assembling only crossing-overs.

**Theorem 1.** The whole space  $H^n$  is the ancestral population if and only if there are the elements in the primary population  $P$ , which have the following properties: for each locus, we have two elements from  $P$  having different (in terms of dual opposing) values (the proof in Pliszka and Unold (2011)).

As a conclusion of the above Theorem 1 we have convenient

**Theorem 2.** If a primary population  $P \subseteq H^n$  contains the pair of polar chromosomes, then the whole space  $H^n$  is a ancestral population, where two points  $h_t$  and  $h_k$  in  $H^n$  are called polar chromosomes if and only if for each coordinate these points have opposite values.

For example, having two polar chromosomes  $h_0$  and  $h_7$

Figure 1: Exemplary ancestral binary population in Hadamard encoding with the primary population  $h_0$  and  $h_7$ .

as a primary population from  $H^3$  we are able after three crossovers obtain all 8 chromosomes from the space in question, according to Theorem 2 (see Figure 1). What is interesting is that more crossover operations are needed when using natural selection and random points of crossing.

Theorem 2 allows us to determine the number of necessary and sufficient one-point crossovers, we need to recover the entire space  $H^n$  from the two polar chromosomes.

**Theorem 3.** Any algorithm established to restore the entire space  $H^n$  from two polar chromosomes with a one-point crossover operator needs at least  $2^{n-1} - 1$  operations (the proof is omitted).

Moreover, it is possible to construct such an algorithm, which reconstructs the whole binary space exactly in  $2^{n-1} - 1$  steps.

Note that introduced representation allow us to distinct and classify different populations, what is more to penetrate into the potential future directions of their evolution regardless of the selected crossover algorithms, selection of parents, or the elimination of individuals. Having Theorem 3 we are able to compare GAs in terms of efficiency and optimization.

## Abstract

In this paper we challenge the notion of ‘normativity’ used by some enactive approaches to cognition. We define some varieties of enactivism and their assumptions and make explicit the reasoning behind the co-emergence of individuality and normativity. Then we argue that appealing to dispositions for explaining some living processes can be more illuminating than claiming that all such processes are normative. For this purpose, we will present some considerations, inspired by Wittgenstein, regarding norm-establishing and norm-following and show that attributions of normativity to non-social agents are deeply paradoxical. The main conclusions of our discussion are: (1) circular and internal explanations centred on the stability of living systems are insufficient to account for processes where the environment plays an important role, such as adaptation. Enactivism is not an explanatory alternative to evolutionary biology but needs it as a complement to accounts focused on the internal self-assembly of organisms; (2) though we share enactivism’s anti-representational spirit, we argue that ecological psychology can offer a better account of perception.

## Enactivism’s natural norms

Enactivism is often presented as the new paradigm for explaining cognition (Stewart et al., 2010). It is based on the assumption that cognition, rather than being a matter of abstract calculus and manipulation of internal representations in the head, is a spatio-temporally extended and dynamical process in which an embodied agent is meaningfully dealing with its environment in order to adapt itself to it. But this is not enough for defining enactivism. In fact, all these assumptions and tools have already been endorsed and developed by other anti-cognitivist theories, such as ecological psychology (Gibson, 1966, 1979). So, what’s new about enactivism? For some enactivists (Di Paolo, 2009) their theory provides a definition of agency in which the new embodied, extended and anti-representational cognitive science can rely on. Enactivism was born as a biological theory that emphasized the continuity between life and mind (Canguilhem, 1965; Maturana and Varela, 1987). Among the impressive achievements of the theory, perhaps the most important was the change of focus in thinking about living creatures: these are not seen as mere compounds of parts selected by evolution, but as whole agents individuated from their environment in terms of their internal structure. This

structure or system is based on different networked processes (such as metabolism and the different processes of the nervous system, for example) and it is taken as a unity. This is to say that the system as a whole provides stability, and the processes of this system that result from its stable configuration are intended to keep this unity going. An agent, thus, is autonomous or self-sustained, and its goal is to keep this self-stability. This is the sense in which life is normative, according to enactivism. Although this idea was already being embraced by some philosophers (Canguilhem, 1965; Jonas, 1966) only the explicit analysis due to Maturana and Varela made it into a suitable starting point for thinking about cognition. Cognition is one species in the wider genus of adaptive processes. Adaptive processes come in the form of a coupling typically described in mathematical terms; something that has been called the ‘agent-environment coupling’. In the context of perceptual processes, which are a special kind of adaptation, this coupling is called the ‘sensorimotor loop’. A refined notion of adaptation (in the first, broader sense) was developed later in the enactivist framework for clarifying how all these concepts are interrelated (Di Paolo, 2005).

Given the former definitions, we can broadly distinguish between two varieties of enactivism. First, those that endorse the biological notion of agency as a self-sustaining system along with the idea that perception is based on a sensorimotor loop. Second, those that are only committed to this way of explaining perception and do not hold to the theory of biological agency that defines the first group. Among the latter authors we can find Noë (2005) and O’Regan (2012). Conversely, among the former theoreticians we can find Maturana and Varela (1987), Jonas (1966) and others. We will focus on the notion of ‘normativity’ provided by the latter group, and for this purpose we will analyze the most recent definition of this phenomenon: the one provided by Barandiaran et al. (2009).

This approach to normativity is given in terms of its co-emergence with individuality and action, and these three notions work as different conditions for agency. Also, this agency is at the service of the autonomy of the system. So, given the fact that living systems are autonomous or self-sustained, for enactive philosophers a prior assumption is required in order to understand how agency emerges. For the enactivists, the difference between machines and living beings is that for machines “no *intrinsic force or process* is lumping the components together, nor has the system as a whole (independently of us) a specific way of functioning and

*demarcating itself from the rest*” (Barandiaran et al., 2009; emphasis added). The individuality of the entity is not projected but recognized when we deal with living beings. The entity itself displays to us its own criterion of demarcation from the environment: an agent is then “a system capable of defining its own identity as an individual and thus distinguishing itself from its surroundings; in doing so, it defines an environment in which it carries out its actions” (Barandiaran et al., 2009, p. 3; the quotation appears in italics in the original).

But a question remains unanswered: what is the particular process (or force, as it is quoted above) that allows for this demarcation? The answer is nothing but its own actions: “agents define themselves as individuals as an ongoing endeavor and *through the actions they generate*” (Barandiaran et al., 2009, p. 3, emphasis added). So, agents, by means of their acting, demarcate themselves as independent entities — and in doing so, they define themselves and also define the environment in terms of exclusion.

Here we arrive at a crucial point: if the definition of individuality comes by means the agent’s actions, how do we differentiate mere random movements from genuine actions? When we talk of an action-perception loop in order to describe the interaction of the agent with the environment we cannot consider that both parts are equally active in the interaction. The coupling of a leaf flowing in the air establishes a symmetrical relation: the weight of the leaf and the force of the wind regulate the process with the same degree of implication. As we have seen, living beings are different: they act upon the environment and thus they can be demarcated from it. This is an asymmetrical relation. Agents and environments do not play the same role in the coupling. Hence the sensorimotor loop (or any other coupling) is not like the leaf-air coupling: it is something provoked by the agent. Actions are not random because the agent tries to achieve a certain goal with them. An action is a goal-directed, normative movement. That purposiveness demarcates actions from other movements. Thus, “*agents have goals or norms according to which they are acting*, providing a sort of reference condition, so that the interactive modulation is carried out in relation to this condition” (Barandiaran et al., 2009; emphasis added). The statement quoted above is highly revealing: goals and norms are used interchangeably (Barandiaran et al., 2009, p. 5, footnote 2), and these norms are the reference condition by which we can say that agents are acting. Furthermore, the coupling with the environment is carried out in relation to this normative character that specifies the kind of interactions with the environment that are defined as ‘actions’.

But what is a ‘norm’ from this enactive perspective? Is it a statement or an explicit rule like ‘the queen can move any number of vacant squares horizontally, diagonally or vertically’ or ‘do not feed the animals’? Clearly not. First, no linguistic competence is necessarily involved in the employment of this kind of norm, and nor is interaction with other agents required. Rather, it seems that some process is normative when it establishes and maintains the individuality or self-sustenance of the system: “self production is a process that defines a unity *and a norm*: to keep the unity going and distinct” (Di Paolo, 2005, p. 434; emphasis added). A process

that benefits adaptation is a “norm given by self construction” (Di Paolo, 2009, p. 50).

Now we have the whole picture of enactivist agency: agents are systems that individuate themselves from the environment by means of their actions, and those actions are described normatively. We can talk of a *co-emergence of individuality and normativity*: even though enactivists separate these as different conditions, they also explain in what sense the two concepts are co-extensive or interrelated. It can be useful to briefly return to the quotes cited above: “agents define themselves as individuals as an ongoing endeavor and *through the actions they generate*” and “*agents have goals or norms according to which they are acting*”. This amounts to saying that individuality is defined in terms of action and action is defined in terms of normativity. So, it is this “*deep circularity* and *entanglement* between networked processes, the self-maintaining conditions they generate and the interactions that the system establishes with the environment what [*sic*] makes agents so challenging to model and understand” (Barandiaran et al., 2009, p. 8; emphasis added). Recently, Barandiaran and Egbert (in press) modeled the normative behaviour of a unicellular agent based on these criteria. In their model they differentiated between derived and intrinsic normativity, and they claim that the latter is a central feature of living beings, which are able to establish and follow their own norms in order to keep up the self-sustainability of their structure and their ability to adapt to their environments. That is why, for these authors, enactivism is a new paradigm: because it establishes a theory of agency through which we can understand cognition and, specifically, the normative aspect of it.

## Dispositions and norms

The first set of examples that could clarify the notion of ‘normativity’ defined by enactivism comes from the philosophical discussion of dispositions. Several authors have previously appealed to dispositions in order to explain the behaviour of physical objects but also of biological or rational agents (Ryle, 1949; Molnar, 2004; Mumford and Anjum, 2011). We say that sugar has the disposition to dissolve when put into water, neurons have the disposition to open their sodium channels when they receive a stimuli, and humans have the disposition to laugh when they listen to a joke. For some authors, these dispositional properties are defined as intrinsic, first-order, and real properties of agents and objects (Molnar, 2009). By ‘first-order’ we mean that dispositions are properties instantiated in individuals. The claim is that these dispositional properties are intrinsic to their bearers because they do not depend on the existence of any other object. Given these features, we can say for example that the fragility of a piece of glass is a property instantiated in a particular item, and also that the existence of that property does not depend on the existence of any object other than the piece of glass. The realist commitment to the property comes with the conclusion that, given its individuality and intrinsicity, a disposition does not need to manifest itself in order to prove its existence. Glass can maintain the property of being fragile even when it never breaks. We do not need the continuous manifestation of a dispositional property in order to assume its existence. Based on this, a special feature of dispositions is their

directedness: dispositions are directed to their reciprocal dispositional partners rather than to their manifestations. These reciprocal partners are other elements of the same kind that, given the right circumstances, play the role of triggering the manifestation of the property. For example, imagine a sugar cube: a sugar cube has the property of being soluble even when it is not able to show its solubility (let's say, even when it is covered by plastic wrap while submerged in a glass of water). In this case, the disposition exists even when it is not manifested. Also, following Martin (2008), we can imagine that some chemical product A has the property of being soluble when mixed with another chemical product B even if product B does not exist in the universe (e.g., product B has never been synthesized because it would be too expensive to do so). In any event, our realist intuitions towards dispositions incline us to consider that the product A has the property of solubility even if it will never be manifested.

An interesting feature of dispositions is that, applied to biological agents, they cover abilities and natural reactions as well as learned and innate responses. We can say that a dog once had the disposition to growl when the master picked up its bowl, but now it has the disposition to sit down when the master does the same thing. Also, given all the features mentioned above, dispositions can be useful for explaining interaction with the environment in a non-representational way: from a dispositional perspective, the basic unit of analysis is not the agent, but the agent-environment coalition. Dispositions, thus, explain the expected behaviours of certain agents under specific conditions.

Given this account of dispositions, we think that these properties are very useful for explaining different processes and behaviours of living agents, which are highly context-dependent. Thus, we are going to provide an example by which we can differentiate between a dispositional state and a normative behaviour: this will help us to show how the difference between following a rule and manifesting a disposition is blurred in the enactive account of perception. We will conclude that the subsumption of the dispositional within the normative is not helpful for explaining the different cognitive states of living agents. Imagine this situation: Manolo is a heavy smoker. To say that someone is a smoker is to make a dispositional attribution. Manolo is a smoker even when he isn't smoking. Being a smoker is being disposed to smoke a cigarette in certain circumstances (being a heavy smoker is to be so disposed in most circumstances). For instance, Manolo has the disposition to light a cigarette every time he sees one, as if an internal force pushed him to do it. One day Manolo goes to the doctor and he is told that if he continues to smoke, he is very likely to develop a chronic respiratory disease. He realizes that he *must* stop smoking. This realization did not cancel his *disposition* to smoke, at least not in the short term. Nevertheless, it did stop him from *manifesting* the disposition. What was it that stopped a deep-seated disposition from manifesting itself? The answer is clear: a *norm*. A norm can inhibit the triggering of certain dispositions even when the circumstances are otherwise entirely suitable for the disposition to manifest itself. From this perspective, a norm can inhibit but it can also eliminate a disposition after a certain number of corrections. So, the first

difference between a disposition and a norm is that the first is intrinsic and internal, but the second is not. This is why the internal force persists even when the agent follows a rule imposed by another agent (such as the smoker and the doctor). Given these features we can understand now why a norm, then, is different from a disposition. It is clear when we look at examples involving humans, but can this notion of 'norm' be applied to neurons or bacteria? It seems that there is no room for this conceptual tool in the explanation of the behaviour of unicellular agents. *Who* can correct the cell for not behaving in a certain way? How can an intrinsic disposition of a bacterium be inhibited by a norm, if the only dispositions that we can find in bacteria are those that allow for its survival (or, at least, that allowed for the survival of its ancestors)? It seems that there is something in the context of bacteria that is missing if we want to apply the concept of 'norm' to them.

## Wittgensteinian norms

As we've seen, enactivists do not differentiate between *biological* dispositions and norms, and they label all these different processes 'normative'. This would be a minor problem if it were only a terminological issue. However, we think that the problem is also conceptual and ontological: what we have here is a disagreement regarding what a norm *is*, *how* the concept works and *in which context* it can be applied. We have seen that some enactivists claim that a solitary agent can both establish and follow its own norm. Now the question is whether that claim is acceptable. Is it intelligible to think of an agent who is able to establish and follow its own rules in isolation?

We think that Wittgenstein's discussion on rule-following is still very relevant to this question. In the well-known sections of his *Philosophical Investigations* devoted to this issue, he offers a battery of arguments to show that the answer should be negative (Wittgenstein, 1953, §§ 185-242). When we talk of following and establishing our own norm we are talking of establishing and following a special course of action. Wittgenstein wants us to imagine a situation in which somebody is teaching a pupil to count in a certain way and the teacher wonders why, after many repetitions, the student is still not doing it correctly. The first explanation of the student's behaviour is always to appeal to his natural reactions, to his natural inclinations, for answering one way rather than another. This suggests that we can distinguish between acting according to one's natural dispositions and acting correctly — acting according to a rule. So, following a rule seems to be something much more complex than naturally reacting. If all there is to following a rule was to act according to one's brute inclinations, then there would be no situation where learning could be thought to be necessary to coming to act *in the right way*.

If equating norm-following with acting according to one's unlearned natural dispositions is problematic, perhaps the enactivist, in her defense of the idea of biological norms, could appeal to the notion of interpretation. A sphere would be normative inasmuch as its inhabitants were capable of interpreting norms in such a way that their action was a case of following the rule under their interpretation. When discussing whether acting according to a norm can be

understood as offering an interpretation such that the action becomes subsumable by the rule, Wittgenstein comes back to the example of the pupil learning mathematics. After some successful exercises that seemed to show that he had mastered the use of the “+” sign (all involving numbers smaller than 1000), the teacher asks him “how much is  $1000 + 2$ ?” The student answers “1004”. When the teacher tells him that this is not the right answer, he defends himself claiming that he is doing exactly what he was told: “I did as before. Wasn’t the rule: add 2 up to 1000, 4 up to 2000, 6 up to 3000 and so on?” The student has managed to provide an interpretation of the rule behind the use of the “+” sign that covers all possible uses of the sign and is consistent with all of the examples he was exposed to during his learning. It is tempting to say that the pupil can act in accordance with his own criterion. At the very least, he seems to show a personal and systematic way to face stimuli after a number of repetitions and encounters with them. A defender of the idea of non-social, natural norms would argue that the habitual answer to the stimulus can become a norm (i.e., a well-established causal connection). In fact, on what else would the rule-following of an isolated agent depend than on its personal interpretation of the norm (i.e., on its own systematic way of reacting to a given stimuli)?

This way of understanding normativity seems deeply paradoxical: if acting according to a rule is no more than interpreting the rule in such a way that the action falls under it, then every action can be made out to accord with some interpretation of the rule and every action can also be made to conflict with an interpretation of the rule. Then there would be neither accord nor conflict here. If every idiosyncratic interpretation of the rule is right, then how we could say that somebody is wrong? It would seem that the concepts ‘right’ or ‘wrong’, which are tightly connected to the concept of ‘norm’, are of no use here. So, if everything is a norm, then nothing is a norm at all because nobody could distinguish what is normative from what is not. As Wittgenstein claims in § 201: “What this shows is that there is a way of grasping a rule which is not an interpretation, but which is exhibited in what we call ‘obeying the rule’ and ‘going against it’ in actual cases.”

Our claim in this paper is that the idea of a bacterium establishing and following norms is just as problematic as the idea that all there is to grasping a rule is to behave in a way that coheres with some possible interpretation of the rule. To talk about norms is to talk about the possibility of being right and wrong, and this in turns demands that the agent be capable of distinguishing between “it is correct” and “it seems correct to me”. Could anyone make such a distinction without having being corrected in the past? We believe not. Given the fact that the aspirant to being a rule-follower cannot be its own corrector, we claim that rule-establishing and rule-following need to be defined as a socially-mediated phenomenon. Norms can only emerge within a social context; norms are, then, social institutions. Norm-establishing is a social process. That is precisely why norms are external: because the criteria of correctness are shared across a community of agents.

The alternative, solipsistic conception of rule following makes following a rule analogous to speaking a private language (i.e., to following private, internal linguistic norms).

Norms must be guided by certain criteria that determine the correctness of their own applicability. These criteria are external in the sense that a single agent acting alone cannot establish them: if that were the case, senseless situations like the one discussed above would be common. But why is that situation ‘senseless’? Because if somebody follows a rule and she cannot distinguish between following it and not following it, she cannot guarantee that she is following the rule in the right way. This point is explicitly stated by Wittgenstein: “Hence it is not possible to obey a rule ‘privately’: otherwise thinking one was obeying a rule would be the same thing as obeying it” (Wittgenstein, 1953, § 202). So, where do rules or norms come from? Don’t they come from the agents that establish them? Sure, but this is not the same as saying that a solitary agent could be involved in the process of establishing a rule. Norms can only emerge within a social context.

Rule-establishing cannot be a private exercise, but what about norm-following? The enactivist claims: “even if the origin of some norms does not fully lie within the individual (e.g., social norms) it is always the individual who internalizes them” (Barandiaran et al., 2009, p. 6). What sort of process could this internalization be? For the purpose of answering this question, let’s rescue another classic example from Wittgenstein, that of the beetle in the box (Wittgenstein, 1953, § 293). Let’s assume that everyone in their own case knows how to follow a rule because they have internalized it. Each of us would walk around carrying a box and calling what is inside ‘a beetle’ — or, better, ‘a norm’. Nobody can see inside anyone else’s box, and everyone knows what a beetle (or a norm) is only through looking inside their own boxes. On the other hand, we all know how to use the concept ‘beetle’ or ‘norm’. Suppose that in fact we all have different things in our boxes (or even imagine that there is nothing at all in them). The key point here is that the object in the box plays no role at all in our understanding of how to use the concept. In the same vein, we do not need to look inside us or appeal to any inner state to know what following a rule is. The criteria are *outside* the individual; they are located in the social community. They are *shared*. But they are not *objects*. We do not need to look for them as if they were part of our internal machinery. This is why norms are not individual-internal, but social-external processes, both when they are established and when they are followed. Being goal-oriented and having conditions of success and failure is necessary but not sufficient for being normative. Normativity also demands awareness of the possibility of error, training, habit and social learning.

## Conclusions and further work

In this paper we have offered three inter-related arguments against enactivism’s insistence on talking about norms at the level of simple, non-social agents: (1) the co-emergence of individuality and normativity is just taken for granted because the claim that these are mutually supporting ideas is viciously circular. A robust notion of agency related to an evolutionary history of adaptation and selection is sufficient to account for the singularity of living systems. (2) A notion of normativity as vague as the one offered by the enactive theory blurs the distinction between dispositional, individual, intrinsic natural processes and the social, external and institutional ones that

can inhibit the former group. A clear separation between phenomena defined by mere conditions of success and failure and phenomena characterized by correctness conditions makes explicit such a distinction. (3) The concept 'norm' can only be applied to what enactivists call 'social norms': the Wittgensteinian discussion of rule-following shows that there is something deeply paradoxical in thinking of the behaviour of an agent considered in isolation as being governed by norms. As usual, we should not be led to confusion by etymology: full-blown normativity and self-regulated behaviour are to be distinguished. A single agent cannot establish a rule because it is acting according to its dispositions; acting according to one's dispositions and acting according to a rule are not the same thing; and, finally, there is no need to appeal to any internalization of the norm to explain how agents follow them.

The behaviour of a cell is manifestly suitable for explanation in dispositional terms, because it cannot be divorced from its environment. We can say that its behaviour is rich enough to qualify it as 'goal-directed'. But it is not normative because there is no socially-established norm that could inhibit any of the cell's intrinsic dispositions. Inasmuch as the criteria of correctness of that hypothetical norm are not shared, the cell could not possibly distinguish between instances when it is acting according to the norm and instances when it is not. Neither could we: the distinction between failure due to the cell's behaviour and failure due to, say, a hostile environment cannot be made for actions that are mere manifestations of dispositions. Our claim is that a cell's behaviour may be insufficient to guarantee its survival in some environment, but that such failure does not entitle us to consider the behaviour incorrect. This is why the only wrong cell is the dead one.

Our qualms with enactivism's excessively liberal use of normative considerations is no obstacle to our sympathy with enactivism's anti-representationalist commitments, as well as its emphasis on embodiment, situatedness, the active character of perception, and the centrality of the agent as a whole. We also agree that perceptual relations with the environment can be explained by means of looping processes. However, we think that this anti-representational approach to cognition is better developed by ecological psychology (Gibson, 1979). Gibsonians gave an account of perception in a way that is much more externalist, biosemiotic, and structure-independent than the sensorimotor contingencies defended by the enactive view. This is the reason why ecological psychology has provided a better account of learning than enactivism, even though they start with the same anti-representational assumptions (Jacobs and Michaels, 2007). Enactivism is too closely focused on the internal structure of the organism and concedes too little attention to the explanatory role that the environment plays with respect to perception and action. We also depart from the enactivists regarding their faith in autopoiesis being the best explanation of every aspect of biological processes: from the emergence of agency to the emergence of perception. We also do not see autopoiesis as being the best explanatory framework for processes such as adaptation and cognition. In fact, as we have seen, the enactive, co-emergent explanation consists in subsuming all biological processes into just one: the recursive loop made by all systems of every organism. This may well be the best

answer to the question of how all organisms are able to maintain their stability through time, but that does not amount to defining agency, adaptation, cognition and the rest of the set of biological processes at once. Take the example of adaptation, a process the enactivists sometimes call 'adaptivity' (Maturana and Varela, 1984; Di Paolo, 2005). This process is based on the recursive loop we have mentioned, and we can apply the same logic of recursivity to the relations of the agent with the environment: an adaptive capacity is one that is able to regulate its relation with the environment in order to keep the agent within a state of viability. Organisms can detect tendencies in which the agent approaches (or recedes from) the boundary of viability. As any biologist would concede, this formulation is insufficient to account for adaptation in the full sense. Adaptation is a trait that contributes to the fitness and survival of individuals but it also needs to be explained as the result of processes of natural selection, and reference eventually needs to be made to species and populations (Darwin, 1859; Huxley, 1942; Williams, 1966; Mayr, 1983). If we want to give a full account of why an agent is adapted, we necessarily need to appeal to its evolutionary history and talk about how natural selection works. This is a question answered only at the macroscopic level and by means of reverse engineering (Dennett, 1995), not by looking at the looping processes of individual agents. We think that the excessive emphasis on the logic of looping processes is leading enactivism towards an underestimation of natural selection, the role of populations, and the different levels of explanation involved. Not all questions in biology are answered by redirecting the answer to the looping processes of self-sustenance of individual agents. Some questions (why a trait has evolved this way rather than that way, *why* we have perceptual system at all, etc.) are answered by appealing to the supra-agential realm and this means by appealing to how natural selection works. Whereas other questions (*how* do we perceive, etc.) are answered appealing to looping processes (ecological, perception-action loops). There are different questions addressed by different levels of explanation. We do not think, as enactive theorists seem to endorse, that all biological processes can be explained by means of their looping and co-emergent logic and by appealing to the autopoiesis of individuals.

We think that this philosophical discussion is clearly of interest for computer scientists for two very important reasons: it is important not to confuse levels of analysis and also not to misattribute properties or predicates to agents that do not fulfill the right criteria of application. An unicellular agent cannot be wrong because there is no room for norms in its behaviour. For following a norm some conditions are needed: (1) a community, (2) the possibility to err, (3) correction criteria for the right application of a concept or a right way of behaving in a certain context, (4) the possibility to differentiate between following a norm and thinking that one is following a norm, (5) to be sanctioned by a community in order to understand which are these criteria and how to differentiate between what one thought she was doing when following a rule and what she was really doing. Even when a Wittgensteinian strategy is not committed to offer necessary and sufficient conditions for defining a concept, these previous points can summarize more or less some features that are common to any notion of 'norm'. We think that,

summarized in the previous points, a computer scientist does not offer anything new when he claims that a unicellular isolated agent can follow norms. That claim only shows that, even when he could design a really good model, the scientist never got the conceptual point of what a norm is. Even though it is surely possible to describe all of the different levels of agency from a naturalistic viewpoint (making use of our best empirical evidence from the biological sciences), introducing the most complex concepts, such as ‘normativity’, when studying the most primitive forms of agency is not a good strategy. A better strategy would be to focus on what have been called the ‘major transitions in evolution’ (Maynard Smith and Szathmáry, 1995); that is, to focus on the conditions under which new organizational levels appear rather than taking them for granted. Unlike enactivism, we reject the idea that the naturalization of normativity can be made by normativizing nature: all that is rational is real, but not all that is real is rational.

## Abstract

The MONEE framework endows collective adaptive robotic systems with the ability to combine environment- and task-driven selection pressures: it enables distributed online algorithms for learning behaviours that ensure both survival and accomplishment of user-defined tasks. This paper explores the trade-off that must be reached between these two (possibly contradictory) requirements, in the case where a foraging task is defined by the user. In particular, we study the impact of enforcing specialisation (i.e. the collective must acquire two mutually exclusive foraging skills) as well as the mechanism for tuning the level of specialisation in an on-line fashion. Results show that the actual behaviour of the collective system can be guided on request during the course of evolution in order to achieve a particular distribution of specialisations, albeit within a certain range of values.

## Introduction

The work in this paper is inspired by a vision of a collection of robots that evolve to survive and operate in an environment where human control can be effected only intermittently. In such circumstances, the robots have to act autonomously, without direct human intervention. They must therefore survive long periods without any guidance and when they do receive guidance, it is at a considerable delay. The environment is not completely known at deployment time and it changes over time, as do the tasks that the robots have to complete. Therefore, the robots must adapt to survive the environment and to perform their tasks.

The environment in which robots operate indirectly circumscribes goals for the population of organisms to survive and evolve, but does so without specifying objective functions: the robots must for instance move about to spread their genomes, or they must maintain their energy levels, but these goals are not defined directly: it is just that robots that display this behaviour get more opportunities to procreate. By virtue of its similarly unbounded nature, biological evolution has resulted in the high levels of adaptability and robustness that we see in natural living organisms. To exploit this creative potential in a system of evolving robots (or robot controllers), we would want to give evolution

as much freedom as possible, pushing for open-ended, unbounded adaptivity, unconstrained by user-defined objective functions.

On the other hand, if the system is to be of any practical relevance, the robots must of course also perform user-defined tasks, pushing for specific, crisply defined task-related objectives.

Evolution has been employed to achieve both of these facets. Artificial Life research abounds with examples of objective-free evolutionary systems since the 1908s (Langton, 1989, 1995). In such experiments, evolution serves as a force for adaptation. Evolutionary robotics research typically employs evolution as a force for optimisation when it focusses on the task-driven aspect (Nolfi and Floreano, 2000).

Balancing these two aspects of evolution –environment-driven adaptation and task-driven optimisation– represents a vital step towards implementing our vision of autonomous, functional, responsive and self-sufficient robot collectives.

In earlier work, we presented the MONEE (Multi-Objective aNd open-Ended Evolution) to solve the problem of combining objective-free and task-driven evolution in a single algorithmic framework (Haasdijk et al., 2013).

The principal idea behind MONEE is to employ concurrently two selection mechanisms in different roles: environmental selection for open-ended evolution and parent (or mate) selection for task-driven adaptation. As the 'Multi-Objective' part of the name implies, MONEE accommodates settings with multiple tasks. Jones and Mataric noted that collectively tackling multiple tasks also entails a division of work (2003). If there are multiple tasks, the population of robots as a whole must tackle all of them, even though individual robots may specialise in only a subset. To cope with such cases the MONEE framework uses a market mechanism. This mechanism regulates task-based rewards during mate selection according to the market logic that scarcity increases worth. In our multiple task context this implies that tasks that only a few robots (can) perform yield relatively high rewards and therefore higher selection probabilities.

We showed that the MONEE paradigm does indeed allow

the robots to adapt their behaviour to the environment as well as to multiple tasks. Also, MONEE's market mechanism is crucial to keep the population from focussing exclusively on easier tasks, even when the environment induces specialisation in particular tasks at the individual robot level (Haasdijk et al., 2013).

The market mechanism offers an intriguing possibility for intervention in the adaptive process: users can define premiums for particular tasks to (de-)emphasise their importance and promote or prevent their take-up by the robots. This amounts to defining an exchange rate between credits earned for the various tasks. Such premiums provide a straightforward and intuitive method for human-*on*-the-loop intervention in the behaviour of the robot collective.

We perform an experimental analysis of the influence of premium settings in an implementation of the MONEE paradigm where a simulated population of robots has two tasks: it must collect red and green pucks. The experiment is set up so that controllers for each task must be learned separately. In particular, our research questions are:

- To what extent can a premium direct the focus of the robot swarm to a particular task?
- Does a negative premium prevent the robots from displaying particular behaviour?
- How does swarm behaviour react to changing premium settings?

### Related Work

Bredeche et al. describe meDEA (Bredeche et al., 2012), an open-ended evolutionary algorithm where autonomous robots move around an arena while continually broadcasting their genome over a short range. Meanwhile, they also receive genomes from other robots that come in communication range. When a robot's lifetime expires, it randomly selects one of the received genomes, modifies that using mutation and starts a new life of broadcasting this new genome. This set-up promotes, with only environmental selection, robot movement through the environment: genomes that cause the robot to move around a lot are spread at a much higher rate than genomes that cause their host to stand still.

Similar settings have been extended with forms of parental investment, for instance in Mascaro et al. (2005); Ventrella (2005); Schwarzer et al. (2010). In artificial life parental investment is often used to give the offspring a starting value of (virtual) energy (Menczer and Belew, 1996; Menczer et al., 1994; Burtsev et al., 2001; Scheutz and Schermerhorn, 2005) and a parent's energy level is often linked to task performance (e.g., agents tasked with eating grass to gather energy in Burtsev et al. (2001)). Distributed on-line evolutionary systems such as Watson et al.'s embodied evolution similarly employ task-related (virtual) energy to determine parent and survivor selection (Watson et al.,

2002; Wischmann et al., 2007), typically considering single tasks. These experiments showed that task-related virtual energy (equivalent to credits for appropriate behaviour) is an effective way to guide evolutionary adaptation to tackle tasks.

Market-based schemes provide a well known solution to the task allocation problem in multi-agent and multi-robot settings, for instance in (Walsh and Wellman, 1998; Tang and Parker, 2007).

Fitness sharing is a well-known technique that was introduced to promote genetic diversity and so prevent premature convergence in evolutionary algorithms. With fitness sharing, an individual's fitness is reduced if there are many similar (in terms of their genetic makeup) individuals in the population. Traditionally, fitness sharing is not necessarily associated with multiple objectives, but with maintaining diversity in general – typically, but not exclusively, in single-objective settings.

### MONEE: Multi-Objective & Open-Ended Evolution

As mentioned above, earlier work showed that MONEE effectively combines environment- and task-driven adaptation (Haasdijk et al., 2013). The population of robots shows similar adaptation to the environment with MONEE as it does with its purely environment-driven counterpart meDEA. In addition, the robots learn to perform puck-collecting tasks. They equitably distribute the collective foraging effort over different puck types, even when one type is more prevalent than the other or when the environment inhibits individual robots gathering multiple types of puck.

The robot –actually, their controllers'– lifecycle in MONEE consists of two phases: life and rebirth. The robot controllers have a limited, fixed, lifetime during which they perform their actions; moving about, foraging, et cetera. When their lifetime ends, they enter a rebirth phase and become 'eggs': stationary receptacles for genomes that are transmitted by passing live robots. This rebirth phase also lasts a fixed amount of time, and once this has passed, the egg selects parents from the received genomes to create a new controller. The robot then reverts to the 'life' role with this new controller. Thus, robot controllers can procreate by transmitting their genome to eggs, and the more eggs a robot inseminates, the more chances it has for procreation. Because the transmission of genomes is continuous and at close range (e.g. through infrared), the more a robot moves about the arena, the better its chances of producing offspring. This aspect of MONEE is open-ended in the sense that it is objective-free: there is no calculated performance measure that defines the chances of being selected as parent, there is no task. Only the environment and robot behaviour dictates what robots may or may not become parents.

To add task-driven parent selection to this basic evolutionary process, the robots can, during their lifetime, amass

credits by performing tasks. For instance, a robot could get one credit for every piece of ore it collects, one for successfully solving some puzzle, and so on. If multiple tasks are defined, the robots maintain separate counts for the credits awarded for each task, for instance one counter for the pieces of ore collected and another one for the number of puzzles solved. When a robot inseminates an egg, it passes the current credit counts along with the genome and the egg uses that information to select parents when it revives. This scheme is reminiscent of parental investment, but it differs subtly yet crucially from most parental investment schemes: a parent does not actually invest when impregnating an egg because the credits aren't *transferred* but *copied* at no cost to the parent.

When a robot's egg phase finishes, it compares the parents' credits for each genome it has received. To enable this comparison across tasks, the egg calculates an exchange rate between tasks. This ensures that genomes that invest in tasks for which few credits are found overall (presumably hard tasks) are not eclipsed by genomes that favour easier tasks.

The credits relate task performance to reproductive success: besides the open-ended goal of 'merely' transmitting genomes to eggs, robots must also become proficient at the defined tasks for these genomes to be selected. The more proficient a robot is at a task, the higher its chances of procreating. The comparison of credits across multiple tasks introduces an exchange rate between the earnings per task: the more common credits are for a particular task, the less their worth and vice versa. Thus, parent selection becomes a marketplace for skills and features that the user requires. This system naturally caters for multi-objective approaches.

MONEE's market mechanism is similar to fitness sharing in the sense that it also reappraises fitness, favouring tasks that are less commonly tackled by robots in the population. A crucial difference with traditional fitness sharing is that MONEE considers an individual's *behaviour*, not its genetic make-up (reminiscent of *syntactic* fitness sharing in genetic programming (Nguyen et al., 2012)). Hence, it does not promote genetic, but behavioural diversity: it modifies fitness not to prevent premature convergence, but to ensure that the robot population tackles multiple tasks.

It also allows the user to prioritise tasks in a straightforward manner: the user can influence the credit comparison by defining a premium for some or all of the tasks. For instance, if she deems collecting ore more important than solving puzzles, she can define a premium for collecting ore; the credits earned through this task are then multiplied by the premium. Compared to not defining a premium (or defining a premium of 1), setting a premium  $> 1$  increases the payoff for the relevant task, setting it between 0 and 1 reduces it, while setting it to a negative value causes the robot adaptation to shy away from the task.

The pseudo-code in algorithm 1 details the credit comparison market mechanism with premiums defined.

```

for every defined task do                                // total credits
  for every received genome do
    creditstask ←
    creditstask + (premiumtask · genome.creditstask)
  end
  creditsoverall ← creditsoverall + creditstask
end
for every defined task do                                // exchange rate per task
  ratetask ←  $\frac{\text{credits}_{\text{overall}}}{\text{credits}_{\text{task}}}$ 
end
for every received genome do                              // credits per genome
  for every defined task do
    genome.rating ← genome.rating + (premiumtask ·
    genome.creditstask · ratetask)
  end
end
                                                                    // select, mutate and revive
parent ← rank_based_selection(received_genomes)
child ← mutate(parent)
reactivate(child)

```

Algorithm 1: MONEE's market mechanism

## Experimental Set-up

We implemented the MONEE algorithm in a simple 2D simulator called RoboRobo (Bredeche et al., 2013). In our experiments, 100 simulated e-pucks are placed in an environment that contains obstacles and pucks. The sides of the square arena are roughly 330 robot body lengths long (1024 pixels in the simulator), and it contains a number of obstacles (see Fig. 1). We run 64 repeats of each experiment.

There are two types of puck: green and red, defining a concurrent foraging scenario. Concurrent foraging is a variation of regular foraging where the arena is populated by multiple types of objects to be collected (Jones and Mataric, 2003), rather than just a single resource. In our case, these objects are green and red pucks and the collection of each different colour is a different task. The pucks are distributed throughout the arena, and they are immediately replaced in a random location when picked up. The (re-)placement of pucks is governed by a 2D gaussian distribution centred on the middle of the arena and with  $\sigma$  of half the arena width. The robots move around the arena, spreading their genome as they encounter eggs and dying when their allotted time has passed. They collect pucks simply by driving over them and the more pucks they gather, the more likely their genome is to be selected once an egg they impregnated revives.

Figure 1: Experiment arena.

To detect pucks, the robots have 16 sensors that detect either red or green pucks (i.e., 8 sensors per puck-type). Each set of 8 sensors is laid out in the same manner as the stan-

ward e-puck infrared sensors: 6 face forward, 2 face to the rear. Because individual puck sensors only detect a single type of puck, collecting one type of puck is a task distinct from (but very similar to) collecting the other type of puck. Thus, behaviour to collect either type of puck has to evolve separately.

Each robot is controlled by a single-layer feed forward neural network which controls its left and right wheels. The inputs for the neural network are the robot's puck and obstacle sensors.

The robot's genome directly encodes the neural network's weights (3 types of sensor  $\times$  8 sensors  $\times$  2 outputs plus 2 bias connections plus 4 feedback (current speed and current rotation to either output) = 54 weights) as an array of reals.

As mentioned, the robots alternate between periods of explorative puck gathering and motionless genome reception. To prevent synchronised cycles among the robots, we add a small random number to each robot's fixed lifetime. This forces desynchronised switching between life and rebirth even though our runs start with all robots perfectly in sync at the first time-step of their lifetime.

At the end of the egg phase offspring is created by selecting a parent from the received genomes as shown in algorithm 1 and mutating the weights in that genome using gaussian perturbation with a single, fixed mutation step size  $\sigma = 1$ . This single-parent, mutation-only scheme is common in evolution strategies that are known to perform well on problems with continuous-valued genomes (Beyer and Schwefel, 2002).

Note that MONEE does not prescribe any particular controller implementation nor any choice of variation operator. The implementation we chose here of an artificial neural network with the weights encoded as real-valued genes provide a convenient, flexible and well-established representation.

Table 1 summarises the experimental set-up. The paragraphs below describe our experiment's variants in detail. Code for the experiments is available at [http://pages.isir.upmc.fr/evorob\\_db/moin.wsgi](http://pages.isir.upmc.fr/evorob_db/moin.wsgi).

**Premium** It is straightforward to (de-)emphasise particular tasks in MONEE by simply putting a premium on credits earned for that task. To investigate how premiums influence adaptation, we apply premiums ranging from -1 to 100 to the task of collecting green pucks, including a number of runs where the premium is redefined during the run. The premium for red pucks remains constant at 1.0.

During parent selection, the premium is used as a multiplication factor for the number of green pucks collected. Thus, with a premium set to -1, robots collecting green pucks are penalised. A premium of 0 means that there is no benefit to collecting green pucks: only red pucks are considered for parent selection. A premium of 1 means that red and green pucks contribute equally to the chance of a

genome being selected, and higher values increase the importance of collecting green pucks.

**Mutually exclusive skills** Equitable task distribution is more challenging when the tasks that the robots must perform are to some extent exclusive, for instance because they require irreconcilable skills. To test how premium settings affect the MONEE paradigm in such situations, we also run experiments where the environment constrains multi-skilled robots so that the robots must specialise in collecting one type of puck. Without this constraint, robots can collect green and red pucks equally well without any penalty when selecting both or merely one colour. In the mono-skill experiments the speed of robots depends on their specialisation level: the robot's speed is multiplied by the ratio of most prevalent pucks it has collected. Thus, if a robot collects exclusively pucks of one colour, its speed is maximal. If it collects 75% green (or red) pucks, its speed is reduced by 25% and if it collects red and green pucks in equal amount, the speed is halved. This penalty is recalculated whenever a robot picks up a puck. It is important to note that this is enforced by the environment, not during the parent selection phase when an egg revives. The environment causes specialising robots to move faster, so that they perform better than non-specialised robots: their higher speed allows them

to collect more pucks during their lifetime, but more importantly, it allows them to impregnate more eggs. This results in an increase in the proliferation of mono-skilled genomes without altering the selection process inside the eggs.

**Distribution of pucks** Another determinant for the difficulty of task distribution in our experiments is the ratio of puck colours. This can be seen as a proxy for having a difficult (rare pucks) and an easy (common pucks) task. To determine the impact of setting premiums with an uneven distributions of pucks, we run two variants of our experiments: one with 150 pucks of each colour, one with 50 green and 150 red pucks. We perform additional runs with denser spreads of pucks where there are 500 pucks of each colour.

**Changing premium** A last set of experiments explores the evolutionary dynamics in the context of changing premiums. The rationale is the following: what would be the effect on the ratio of harvested puck colours if the premium is reset on-the-fly by a human supervisor? Then, what happens if the premium is changed back to its initial value after awhile? The system dynamics would be more predictable if the harvested pucks ratio matches the original figures, that is evolutionary dynamics always converge to the same ratio values, independent from the initial conditions. It may, however, be expected that the evolutionary dynamics are affected by the behaviour from where it already converged (i.e. the ratio depends from the actual premium *and* from where evolution starts). To explore the influence of changing premiums on-the-fly we use the following set-up: in a setting with the same number of red and green pucks (150 of each) the premium is initially set to 10. After 500,000 time steps, the premium is changed to 1 for 250,000 time steps. It is then reset to 10 for the remainder of the experiment.

## Results and Analysis

**The Effect of Premiums** Figure 2 shows the mean total number of pucks collected in the experiments with 150 green and red pucks. Setting a negative premium predictably decreases the total number of pucks collected: the robots learn to avoid green pucks, in effect halving the number of available pucks. Setting the premium to 0 in the mono-skilled (i.e. with specialisation) environment still results in much lower levels of collected pucks because, again, the robots learn to keep away from green pucks and so avoid the environment's speed penalty for generalist behaviour. This penalty does not apply in the multi-skilled environment (i.e. without specialisation), and the number of pucks collected for premium 0 is markedly higher than with premium -1. The robots now pick up green pucks accidentally and they can take more direct paths to red pucks because they do not have to avoid green pucks. Setting the premium to 1 increases the number of pucks collected: robots now actively

Figure 2: Mean total number of pucks collected over the whole run for different premium settings with 150 pucks of each colour. The vertical bars indicate the 99% confidence interval (over 64 repeats).

seek both types of puck. The mono-skilled environment still causes individual robots to avoid one type of puck or the other, therefore the number of pucks is lower than in a multi-skilled setting. Higher premium values slightly increase the number of pucks collected, but among these values it does not change appreciably.

To assess the impact of premium settings on the task distribution among the robot collective we consider the ratio of green pucks collected ('green puck ratio') over all collected pucks. Figure 3 shows how this ratio develops over time for different premium settings in the experiment with 150 pucks of each colour. Initially, the robot collective always gathers green and red pucks in a 50-50 ratio. With a premium of

Figure 3: Development over time of the green puck ratio for a subset of the premium settings we considered. The points indicate the median green puck ratio for 1,000 time step intervals over 64 repeats, the shaded areas indicate lower and upper quartile.

Figure 4: Mean green puck ratio in the final 1,000 time steps of runs with 150 pucks of each colour. The vertical bars indicate the 99% confidence interval over 64 repeats.

1 red and green pucks are equally valuable and the collective maintains this ratio. A premium of -1 has a profound impact: the robots learn to avoid green pucks and almost exclusively collect red pucks. This setting seems similar to the well-known poisonous food experiment, but the penalty for collecting ‘poisonous’ green pucks is effected during parent selection, not by the environment cutting short lifetime or reducing speed. A premium of 0 also leads to a substantial decrease in the green puck ratio: robots learn to focus on red pucks, but green pucks are not avoided and circa 30% of collected pucks is green. A premium of 10 increases the green puck ratio, which levels off around 0.65. The green puck ratio for premium 0 is in the same range as the red puck ratio for a premium of 10 (circa 0.3 and 0.35, respectively). This already indicates that larger premium values will do little to increase the green puck ratio (a premium of 0 for green pucks would have the same effect as a very high premium for red pucks).

This is borne out by the plot in Fig. 4, which shows the green puck ratio in the final 1,000 time steps of the simulation for varying premiums. We see that the green puck ratio among premium settings of 10 (or even 5) and higher barely changes. We also see that mono-skilled environments increase the impact of defining a premium: obviously, more robots will specialise in the higher rewarding task.

One reason for the lack of additional impact for higher premium values might lie in a saturation effect: if the robots simply cannot gather more green pucks than they do, the ratio can hardly improve. To test this hypothesis, we ran another set of experiments where there are 500 pucks of each colour. Figure 5 shows the results of those experiments. They show the same levelling off of premium impact, so it doesn’t seem to result from a saturation effect.

Figure 5: Mean green puck ratio in the final 1,000 time steps of runs with 500 pucks of each colour. The vertical bars indicate the 99% confidence interval over 64 repeats.

**Uneven Distribution of Pucks** We use a setting where there are more red than green pucks (150 vs. 50) as a proxy for having easy and hard tasks. In these experiments, the ‘natural’ green puck ratio is 0.25, which is what we see in Fig. 6 when the premium is set to 1 in a multi-skill environment. When the environment discourages generalists, the ratio is slightly lower because robots tend to specialise in the simpler task (earlier work showed that MONEE’s market mechanism plays a crucial role here (Haasdijk et al., 2013)). As was the case in the two scenarios where the puck distribution is balanced, increasing the premium past 5 or so has little further effect. The green puck ratio levels off between 0.3 and 0.4 for all premium values of 5 and greater.

Figure 6: Mean green puck ratio in the final 1,000 time steps of runs with 50 green and 150 red pucks. The vertical bars indicate the 99% confidence interval over 64 repeats.

Figure 7: Development over time of the green puck ratio with changing premium with specialisation. The vertical red lines indicate when the premium is reset from 10 to 1 and back to 10. The points indicate the median green puck ratio for 1,000 time step intervals over 64 repeats, the shaded areas indicate lower and upper quartile. Green puck ratio for a constant premium of 10 shown for reference.

Figure 8: Development over time of the green puck ratio with changing premium without specialisation. The vertical red lines indicate when the premium is reset from 10 to 1 and back to 10. The points indicate the median green puck ratio for 1,000 time step intervals over 64 repeats, the shaded areas indicate lower and upper quartile. Green puck ratio for a constant premium of 10 shown for reference.

**Varying Premium Settings** Figures 7 and 8 show the puck ratio over time with changing premium with specialisation enforced and a multi-skilled setting, respectively. Note that we ran the experiment with changing premium for a further 1 million time steps to gauge long-term effects of changing premiums. With or without specialisation enforced, the green puck ratio initially develops unsurprisingly similar to

the control experiment (using a constant premium of 10). Then, as soon as the premium is set to 1 after 500,000 time steps, the green puck ratio drops to reflect the new prioritisation of tasks. When the initial premium is restored at 750,000 time steps, with or without enforced specialisation, the green puck ratio starts to rise again quickly and levels off where it was before the premium was changed. Hence, there is no memory effect when we change the premium in the course of a run, advocating for stable attractors that depend only from the premium value at hand. The change in puck ratio as a reaction to varying the premium is considerably more pronounced in the single-skill setting than when robots can collect both types of puck.

## Conclusions and Future Work

Experimental results on the effects of premium settings with the MONEE algorithm showed that setting premium values stand as an efficient mechanism to allow the user to control the prioritisation of tasks. On the one hand, setting negative premiums dramatically decreases the take-up of tasks. On the other hand, positive premiums enable to promote tasks, at least to some extent. Indeed, the relation between premiums and task distribution is not linear as the influence of increasing premium values is dampened after an environment-dependent threshold.

In the particular case of foraging with two kind of pucks, further experiments showed that controlling the evolution of a particular foraging behaviour is sensitive to the distribution of resources. Enforcing specialisation (i.e. penalising robots that forage both resources) can greatly increase controllability whenever both resources are available in equal amount, while dramatically decreasing controllability whenever an uneven distribution of resources is considered.

Lastly, controllability was also tested from the perspective of on-line tuning, i.e. changing premium values during the course of evolution to match user requests. Results revealed that premium values actually matched very stable attractors towards (expected) foraging behaviours.

Although the work presented here shows that collective foraging behaviour can be controlled to some extent through setting premium values, the non-linear (and thresholded) relation between premium values and task distribution remains to be further explored. We are indeed currently investigating the thresholding of the premium effect. Also, we are addressing the problem how to actually use premiums to automatically achieve a particular state of task distribution. To some extent, this is an inverse problem: while the desired task distribution may be known before hand, the method for tuning the premium values may well depend on the environment and the task at hand.

## Abstract

This paper examines the relationship between flocking behaviour and leadership. In order to achieve this aim, we simulate two co-evolving populations of robots: predators and prey. Behavioural and quantitative analysis indicate that a well-structured hierarchic leadership emerges in the population of predators after the evolution. The emergence of leadership relates to high levels of fitness, so leadership seems to be a winning strategy. We show that the leader role has been assumed by more explorative individuals. Moreover, exploratory behaviours mostly appear when there is a low following behaviour. Therefore, exploratory and following capabilities seem to be complementary both within every replication and within simulations with different perceptual conditions. On the other hand, leadership seems to be a strategy to enable followers to be more explorative.

Index Terms: Leadership, Evolutionary Robotics, Flocking

## Introduction

For the modern ethology and biology, groups of animals are autonomous units, enabling members to synchronize some activities, such as collective foraging and coordination in moving (Reebs, 2000). Specifically, the role of Leadership involves different degrees of conflicts. Across species, individuals are more likely to emerge as leaders if they have particular morphological, physiological, or behavioural traits increasing their propensity to act first in all the coordination problems. The consistent correlation between leadership and personality suggests the intriguing possibility that personality differences are maintained in populations, because they foster social coordination (King, et al., 2009). Many theoretical works have focused on how navigational information is exchanged between group members and how such information flow depends on the knowledge held by each member (Couzin, et al., 2005). In one study, the authors have examined the factors contributing to the formation of leadership/followership patterns in flocks of pigeons, focusing on the role of previous navigational experience (Flack, et al., 2012). The results prove that, in order to negotiate joint routes, pigeons make use of a complex decision-making system based on leadership mechanisms. Basically, less experienced birds are likely to follow more experienced conspecifics. All the pigeon groups exhibited a flocking behaviour. Flocking behaviour can be defined as the

capability of group's members to follow other individuals drawing those typical "lines", which are called "flocks". These behavioural patterns have been extensively identified by biologists and ethologists in the animal world: researchers tend to make distinctions between the "shoaling" behaviour of fish, the "swarming" behaviour of insects and the "herding" behaviour of land animals. Generally, flocking behaviour is used to identify groups of flying birds, the lines they trace are named "flocks" for this reason (Barnard, 1980). Recently, flocking has been simulated in many computer simulations with the aim of understanding the fundamental mechanisms (Kwasnicka, et al., 2007).

Researchers in robotics and agent-based modelling have usually focused on homogeneous groups. In one approach, they have evolved a team of four homogeneous robots for dynamically allocate roles through bodily and communicative interactions (Gigliotta, et al., 2009). In particular, evolved robots show a differentiation in both their communicative and non-communicative behaviours so that only one robot assumes the role of group leader. In another experiment, a group of agents were simulated for the task of reaching a target in a two dimensional environment (Gigliotta, and Miglino, 2007). Lastly, some researchers have evolved a robot colony to study the possibility for the evolution of leadership patterns (Lee, et al., 2011). In this work each robot has a prearranged social position, such as, leader, follower, and stranger.

In the present paper we discuss an experiment focused on spontaneous leadership emergence mechanisms (namely without any prearrangement of the social roles). The Robots were evolved by the use of Evolutionary Robotics techniques. This experiment has a two-pronged value, one for robotics, one for social science. In robotics: the genetic differentiation of robots' control systems could contribute to build a new generation of autonomous robots with a leadership/followership hierarchic structure needed for navigational tasks in an undiscovered environment. For social sciences and artificial life, it may be possible to answer some interesting questions related to leadership, such as: Is leadership unavoidable for a social decision-making problem? What are the characteristics and skills of a leader? How environmental and individual characteristics affect the emergence of leadership? What is the ratio between the leaders' portion and followers' portion in a group? The final two questions would be: What is the relationship between flocking behaviour and leadership patterns emergence? Does

leadership arise in any flocking groups or flocks without leaders could exist?

## Experimental Setup

### The Task

A group of 40 simulated robots live in an environment consisting of a 550cm x 550cm squared arena surrounded by walls. Each robot is inspired by the Khepera Robots bodies, which have circular chassis with a diameter of 5.5cm. The robots' bodies are equipped with visual sensors and two wheels by which the robots move in the environment (see Figure 1). Figure 2 depicts a schematisation of the experimental setup. The environment contains 20 predator robots and 20 prey robots. The only physical difference between the predators and the prey is the colour: blue for predators and green for prey. Both predators and prey are evolved using Evolutionary Robotics methodology (Nolfi, and Floreano, 2000). When a predator robot bumps against walls or against another predator robot, it bounces back in the neighborhood of the contact point facing a new (i.e. randomly chosen) direction.

Figure 1: Schematisation of top and bottom view of the robot chassis.

These bumping rules are followed by the prey robots too, with the exception of bumping into the predators. In fact, there are further behavioural difference between predators and prey: whenever a predator's body approaches and touches a prey's body, the prey disappears, meaning that the predator eats it and the prey consequently dies. On the other side, predators cannot die, in this model. Another substantial difference between prey and predators consists of the different fitness function (which will be illustrated in the next paragraph). The vision system of both prey and predators is based on a linear retina made of 9 photoreceptors (R0-R8) that perceive gray scaled colours. The field of view (FOV) of each robot is 90 degrees wide and represents the extent of the observable world that the robot is able to see at any moment. The FOV ranges from -45 degrees to +45 degrees with respect to the face direction (0°), which is the robot's moving direction. In this way, each photoreceptor manages a 10° wide portion of the FOV: the first photoreceptor is associated to a range of [-

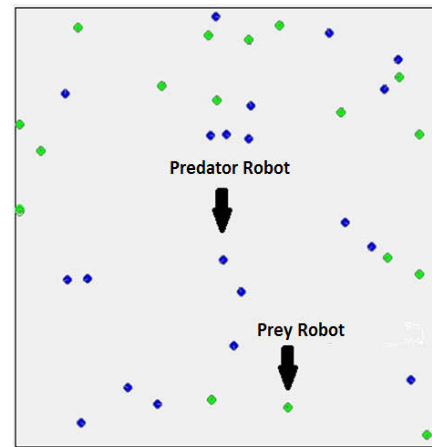

Figure 2: The environment and the robots.

45°,-35°] with respect to the direction faced, the second one to [-35°,-25°], and so on.

When an object (for instance another robot) is located in front of a photoreceptor (within its own vision angle), it is activated to a value encoding the colour of the object. Perceived colour values are grey-scaled by the retina system and normalised in the range [0,1]. Therefore, the prey's green colour activates the photoreceptors at 0.26, which is the normalised value relating to the gray scaled green. The predators' blue colour enables photoreceptors at 0.97. The maximum vision distance for each retina sensor is 55cm. So, if an object is further from a photoreceptor than 55cm, it cannot be detected.

### Neural Controller

An Artificial Neural Network (ANN) controls the behaviour of each robot. The neural network consists of 3 layers with 13 neurons in total: each neuron is connected to the other layers with no recurrent connections. This feed forward topology is schematised in Figure 3. The input layer contains 9 neurons which encode the output from the 9 retina's photoreceptors. In other words, input units receive values (normalised in a range between 0 and 1) from the retina's sensors depending on the gray level of the perceived image. The hidden layer consists of 2 units, and the output layers are the controllers for the motor units: output neurons encode the speed of two wheels which enable the robot to move within the environment. The activation of all the network's units are in the range [0,1]. Internal and output neurons are characterised by a sigmoid activation function (logistics).

### Artificial evolution

The evolutionary process for the robots is based on a ranking type genetic algorithm. Each individual is identified by a genotype that encodes the neural network's parameters. These encoded parameters represent the synaptic connection weights and biases.

Figure 3: The control system of predator and prey robots.

Furthermore, initial parameters are randomly generated in the range  $[-5, +5]$ . Lastly, each parameter is encoded as a sequence of 8 bits. Thus, initially, the environment is populated by a generation of completely “naive” robots (namely, with a randomly generated genome) with no skills on how to move and detect the food sources. In each generation, 40 individuals are inserted into the environment and left to act randomly there. The originality of the algorithm is that individuals are evaluated all together in the environment. In this way, all the robots present in the environment (both prey and predators) in a given moment are characterised by a different genotype that makes them unique in the population (genetic heterogeneity). At the end of each generation, a different ranking and mutation process is applied to both prey and predators, in order to simulate two different species. Each generation is made of 20 epochs. At the beginning of each epoch, every robot starts from random positions. The life time consists of 3,000 time steps. At the end of their life, all the 20 predators are ranked according to the average number of prey eaten in all the epochs. Each of the 4 higher-ranked predators generates 5 offspring which inherit the genotype of their father. The first preserves its father’s genotype entirely (elitism) whereas the rest of the offspring’s genomes receive a random mutation with a rate of 2%. The total number of new predators ( $4 \times 5 = 20$ ) populates the next generation. Similarly, the 20 prey robots are ranked separately. All the evolutionary process carries on for 300 generations. All the simulation is repeated for 10 replications (or seeds).

The Fitness function is computed differently for predators and prey: when a predator bumps against a prey robot, the prey disappears from the environment (i.e. it is dead) and the predator’s fitness score is increased by a value of +1.0.

Each predator robot always lives 3,000 time steps. Whereas each prey robot can die at any time, so prey can have a shorter life span than the predators. A prey’s fitness is calculated by the number of time steps in which it can survive.

## Results

After the evolution, we observed that the predators evolve the ability to run after the prey, and preys evolve the skill of escaping from predators. Moreover we have noticed the emergence of a flocking behaviour between the predators. On the other hand, the prey do not display any specific grouping behaviour, they just tend to explore the environment. The prey simply avoid the predators when they are in the neighbourhood.

Average predators’ fitness curves reveal a constant trend for the best and average populations, as showed in Figure 4.

Figure 4: Visualisation of the average of all 10 predators’ fitness curves, bests (black) and averages (light grey).

The steadiness of fitness curves is present for both predators and prey. In spite of fitness constancy, predators and prey improve their skills and performances throughout the generations. This effect has been explained in other related works by the “arms-races” effect (Nolfi, and Floreano, 2006).

In practice, arms-races may emerge in every situation where a co-evolution of two species is present. That is why, in our simulation, fitness curves appear stable. Nevertheless, robots’ strategies and skills improve and become more efficient during the evolution: predators become faster to hunt prey and prey become smarter to avoid predators. Another factor that makes predators’ fitness curves constant in time, is the fact that, in each generation, only 20 prey can be eaten in total, because the prey will not be replaced in the environment after they die.

To find a single indicator on the fitness reached by robots in each replication, we have calculated the average of average fitness over the last 20 generations (Fitness Indicator).

Apparently there is an unexpected inter-replication variation of fitness. So the first question we have tried to answer is: What is the phenomenon behind the substantial inter-seed variation of average fitness? In order to understand the reason of this variation, we have tried to calculate a static aggregation measure of the predators’ populations in the ecological environment. From this point we only consider the predators’

population for further analysis, as there are no interesting emerging social behaviours in the prey population for our aim. The “Aggregation Measure” has been calculated by measuring the distance between each robot and the nearest robot, in each time step, for the last generation’s populations. All the time steps and epochs measures have been averaged. The lower values correspond to more aggregation and, vice versa, higher values correspond to less aggregation.

By running a correlation between the Fitness Indicator and the Aggregation Measure, the Pearson’s Correlation Coefficient between those two series of data is  $\rho = -0.7$ , which indicates high reverse-correlation between Fitness and Aggregation.

This means that the higher the aggregation, the higher the fitness. In Figure 5 all the series are reported on a plot with the correlation coefficient.

To better understand the mechanisms underpinning the flocking, we have tested each single predator in a reduced environment called “Laboratory”. Laboratory is a square with a size of 150cm x 150cm. Firstly, we have inserted a single predator into the environment, and we have plotted the individual trajectory, as illustrated in Figure 6a.

Figure 5: Correlation between Aggregation Measure and Fitness Indicator.

Some robots display a small exploratory ability, others a medium exploratory ability, and other robots have a large exploratory ability. By placing the robots side by side in the same environment, we observed the behaviour illustrated in Figure 6b. We have noticed that, almost in every couple, one robot always leads and one robot follows. From these observations it appears that the flocking seems to be regulated by a hierarchy among the predators and this is predetermined in advance by the evolution, this hierarchy is numerically proved by exploration measures illustrated later on. We have supposed the hierarchy is guaranteed by every single trajectory (i.e. by every single exploratory ability). On the other hand, the hierarchy cannot be regulated by the colour, because all the 3 robots have the same colour. Exploiting the information from retina photoreceptors, each robot is able to discern the angle of another robot’s movements. In other words, each robot is able to discriminate the arching amplitude of the curvilinear trajectories that another robot is

able to draw. By this amplitude information, robots can recognize the hierarchic degree of their partners.

Thus, every robot is capable to decide whether to follow or to lead, by using this strategy. The leadership appears to be “relative”, namely each leader is not an absolute leader but may be a follower of another robot.

To clarify and support these hypothesis returned by the behavioural analysis, we have developed a series of analytical measures. The first Measure, that we have conceived, is called “Leadership Measure by Vision”, which measures each predator’s leadership hierarchical rank by exploiting the vision system. We have inserted all the possible predator couples into the Laboratory Environment. Each of the 20 predators have been paired with each of the 19 others. For each sub-test, only 2 robots are present in the environment, in the same time. Then, we have counted in how many time steps each predator sees something, namely how many time steps at least one retina photoreceptor is activated. The hypothesis is that if there are only two individuals in the same environment, the leader will see less than the follower, if there are no other objects.

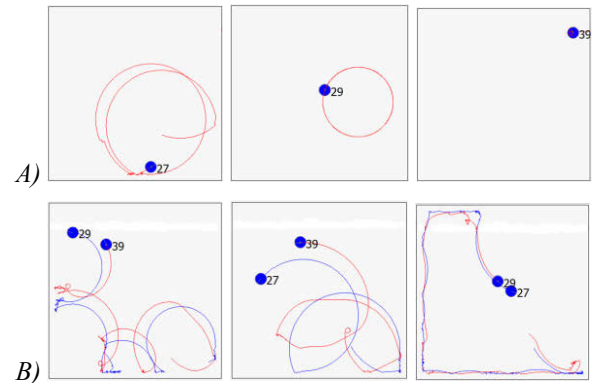

Figure 6: (A) Trajectories of some predator exemplars. They are predator number 27, 29 and 39. Trajectories of predators couples.

In fact, the leader should more likely be at the head of the line whereas the follower should be on the tail.

Correlation Coefficient between “Aggregation” and “Leadership Measure by Vision over replications” has returned a  $\rho = -0.8$  that proves a strong reverse-correlation between leadership and aggregation. This correlation is shown in Figure 7. This means that the higher the leadership, the stronger the aggregation in the group. The reverse-correlation appears because of the design of the leadership measure: the higher the leadership measure, the lower the vision value.

We can argue that, if the aggregation correlates with the fitness, and fitness correlates with leadership, then the leadership correlates with the fitness. That is, high levels of fitness correlate with high levels of leadership

Another interesting issue is in which way is the leadership role connects with the exploratory ability. Predator robots seem to display different exploratory skills. Hence, we have calculated the exploratory ability for each single robot.

Figure 7: Correlation between Aggregation Measure and Leadership Measure.

Each test has been performed on the last generation's population of predators for 20 trials lasting 3,000 time steps. Each value has been averaged over all the trials and reported on the bar-plot. The ability to explore has been then related with the ability of the predators to follow other robots in the environment.

To this end we have identified a "Exploratory Ability Measure" which is depicted in Figure 8, dark grey bars and a "Followership Measure". We have measured the exploratory ability of each robot in ecology by counting how many 5.5cm x 5.5cm sized cells each robot visits only once. (we call ecology the evolutionary environment to distinguish it from the smallest laboratory environment) in two different conditions: *vision* condition, in which the robot can see any other robots in the environment and *no-vision* condition, in which a robot can only see the prey and it is blind to the other presence of the other predators in the environment.

This test has been executed, both conditions, on the last generation's predators for 20 trials.

We noticed that, the *vision* condition produces an increase of exploratory abilities, especially in those cases where robots were not good at exploration in the *no-vision* condition. The increase of exploratory ability has been schematised in Figure 9. As we can observe in the *vision* condition the less explorative robots became more exploratory. It may indicate that the ability to follow other predators in the group seems to be a mechanism to make the entire group able to become more exploratory with respect to the situation in which they are alone. This could arguably be an effect of the social relationship in the group. We can then suppose that, in those situations where there are many individuals who are not genetically predisposed to assume exploratory behaviours, leadership may facilitates the group cohesion and performance by increasing the exploration.

Another interesting insight derives from measuring the exploratory gap between the *no-vision* condition and the *vision* condition, replication by replication. Essentially, we have averaged all the values of the *no-vision* exploratory ability over replications.

A gap appears between replications (light grey bars): the gap can be regarded as the average ability "to follow" of the robots in one replication.

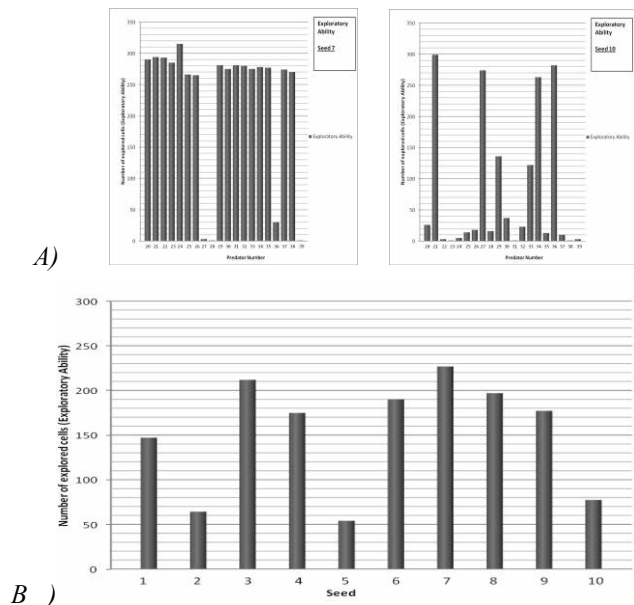

Figure 8: (A) Exploratory Ability Measure. In the picture there are the values of Replication no.7 and Replication no.10. (B) Exploratory Ability Measure over replications (average).

Indeed, we can consider that, from the *no-vision* to *vision* condition, each robot gains an increase of their exploratory abilities, which is directly proportional to the propensity of the robot to follow someone else. If we "isolate" this gap, we acquire a measure of robots' following abilities over replications: the "Followership Measure".

By calculating the Pearson's correlation coefficient between Leadership Measure and Followership Measure the value is  $\rho = -0.79$  confirming a strong correlation.

Figure 9: Exploratory Ability Measure in *no-vision* (dark grey) and *vision* condition (dark + light grey). The light grey values indicate the Followership Measure.

In Figure 10 this correlation is graphically visualised. This indicates that the stronger is the leadership in a replication, the stronger is the followership in the same replication, as indication of the fact that leadership only emerges where the social group is based on a clear leader-follower organization and someone leads and other follows.

Figure 10: Correlation between Followership Measure and Leadership Measure.

The motivation for the flocking emergence is determined by the fact that every predator robot is characterised by a maximum limit of vision distance (55cm), when predators cannot see any prey, they tend to follow another predator rather than doing nothing. This fact is proved in Figure 11 where a chart shows that increasing the vision distance, the following behaviour decreases and vice-versa. The specificity of flocking behaviour is also suggested by the fact that following another predator is notably different than hunting a prey. In fact, when predators move after another con-specific, they do not tend to bump against it, but they just limit themselves to follow keeping a safe distance. Instead, hunting consists of following the prey until the predator reaches it and bumps against it, in order to eat the prey. A careful analysis of the exploratory and following abilities, by means of previous charts, shows another interesting piece of information: the exploratory ability and following ability are reciprocally complementary. This means one ability excludes the other one. For example, in the seed 7, all the predators appear to be explorers rather than followers, whereas in the seed 10 they display an inclination for following rather than exploring. For this reason, we have implemented an analysis of exploration and following abilities depending on different perceptual conditions. In substance, we have re-evolved the robots with different vision conditions, namely by varying the vision distance limit: 13.75cm, 27.5cm, 41.25cm, 55cm, 82.5cm, 165cm and 220cm. We have not been able to sample many more vision conditions because of the elevated computational and time costs of each single evolution. Anyway, the number of completed samples has seemed to be sufficient for the present. The limit of 55cm has been used as the default condition, because it was adopted in the initial evolution. Therefore, we have considered the condition “55cm” as baseline for the comparisons. Again, every simulation has

been evolved for 300 generations and for 10 replications in every vision condition. When all the evolutions have been accomplished, we have calculated the average of the “Exploratory Ability Measure over replication” and of the “Followership Measure”, for each condition.

The result for the “Exploratory Ability” and “Following Ability” through different vision conditions is depicted in Figures 11. We have graphically interpolated all the points in order to highlight the data trend.

Figure 11: (A) Exploratory Ability through different Distance Vision Limits. (B) Followership Ability through different Distance Vision Limits.

## Conclusions

In conclusion, the experiment reported here indicates that in a population of two co-evolving species of robots, with a genetically variable distribution of skills, flocking and leadership are often observed. Although the fitness keeps constant over the generations for the “arms-races” effect, each species’ skills appear enhanced at the end of the evolution: predators are better at hunting prey and prey are better at escaping. An inter-replication variation is present in the indicators of predators’ fitness and aggregation, which underline a different “social” organisation among the predators that we interpret as leadership, which is mainly due to different initial genetic traits (which are randomly selected). In replications where there is a strong component of leadership, there seems to be a stronger aggregation. Furthermore, a strongly structured hierarchy appears in the predator’s population: the rank of each robot is regulated by the explorative attitude of each robot (namely, the amplitude

of movements). Fitness, leadership and followership measures are in strong correlation.

In this way, we guess it is possible to conclude that a group of artificial agents exploit leadership/followership patterns to solve the task of exploring the environment and moving collectively toward the position of the prey. These leadership patterns correlate with higher fitness, which suggests leadership is a winning strategy. In other words, a “peer-to-peer” flocking behaviour is not enough to guarantee a smart movement of the group, but the emergence of leadership is needed for achieving better performances.

Another interesting result is that all the exploratory individuals do not tend to be good followers and vice versa. This indicates that there is a specialisation of skills in populations, according to different simulated conditions. This suggests a theoretical limit: exploration and following are two complementary skills.

Other interesting future directions could be investigating if the bigger the group size, the smaller the leaders portion. Furthermore, some improvements might be achieved in this simulation by examining, in depth, some of the unclear aspects such as the correlation between leadership emergence and fitness and the relationship between genetic variability and leadership emergence.

# Learning Schooling Behavior from Observation

Brian Hrolenok and Tucker Balch

Georgia Institute of Technology, Atlanta, GA 30332  
 {bhroleno, balch}@cc.gatech.edu

## Abstract

Agent-based simulation is a valuable tool for biologists studying animal behavior, however constructing models for simulation is often a time-consuming manual task, and validation of these models requires a principled approach. We present a framework for using machine learning techniques to automatically construct behaviors from tracking data of live animals from video that can be run in a simulated environment. Using this framework, we provide results for automatically learning the schooling behavior of *Notemigonus crysoleucas*.

## Introduction

The motivation for this work has been to enable the work of biologists that study collective behavior through agent-based models. Agent-based models have been successful in analyzing the behavior of social insects such as ants and bees (Pratt et al., 2005; List et al., 2009), although currently such models are constructed after manual processing of video of the collective behavior of the animal. An automated method for constructing these models would enable more rapid iterative refinement of biological theories by allowing researchers to test hypotheses *in silico* with parameters that would be difficult to manage in real animals, as well as provide a tool for performing principled validation as outlined by Yang et al. (2012).

Figure 1: Workflow for automatically constructing executable behaviors from observation

The manual process of model creation usually consists of frame-by-frame annotation of video of the animals in question and statistical analysis of the resulting data, and the automation of this process can be decomposed into two corresponding subproblems: multi-target tracking of animals in video, and learning an executable model from those tracks. This workflow is outlined in Figure 1. The computer vision community has developed a number of algorithms for solving the multi-target tracking problem in specific domains, including tracking biological agents such as humans and ants (Feldman et al., 2012). Given a tracking algorithm that can produce tracks of individual agents with reasonable accuracy, the task is then to construct an executable agent-based model of behavior from the given data.

## Learning fish schooling behaviors

The schooling of *Notemigonus crysoleucas* is an interesting collective behavior, one example of many types of “flocking” behavior found in nature. While the motion of the group as a whole is generally very complex, Reynolds (1987) has shown that individuals following fairly simple local rules can result in global flocking behavior. If we can then correctly learn a model of how the fish react to the features of their local surroundings, we should be able to reproduce the global schooling behavior by simulating fish in a similar environment that react according to the learned model. This means we need to identify which features of the environment the fish are reacting to, compute those features for each track in the tracking data, learn a mapping from features to reactions, and compute the identified features as part of the simulation.

## Fish sensor features

There are several important features of the environment that effect how individual fish act as part of a school, and how the schooling phenomenon arises in groups of fish. We took inspiration from both classic flocking literature (Reynolds, 1987) and more recent work by Katz et al. (2011) in determining which features to include. From the collected tracking data we compute 13 features: 8 proximity sensors, the

Figure 2: Sensor model for *Notemigonus crysoleucas*

$x$  and  $y$  components of the normalized vector to the school center, the  $x$  and  $y$  components to the nearest obstacle, and a binary (near-far) distance to the school centroid that is one if the fish is within 3 body lengths of the school centroid and zero otherwise. The proximity sensors are thresholded at 4 body lengths, and the obstacle vector and school centroid calculation are both limited to objects within 1m.

These specific features can be thought of roughly corresponding with three of the classic components proposed by Reynolds: the 8 proximity sensors are useful for determining *separation*, the obstacle vector provides a mechanism for avoiding environmental obstacles, and the group center vector influences *cohesion*. Notice that we do not include any alignment term, and as Katz et al. suggest, the apparent group alignment is an emergent phenomenon, not a determining feature that the individual fish react to.

### Fish actuators

In order to learn how the fish should react to a given feature vector, we must also quantify how the observed fish actually moved in response to the computed features. The tracking data includes the position  $(x, y)$  and orientation  $(\theta)$  of each fish at each time step (see Figure 3). From consecutive time steps, we can calculate the change in position and orientation as a rough estimate of the velocity of the fish in reaction to its local environment, as long as the time interval is relatively short (the tracking data we use is computed frame-to-frame from video running at 30Hz).

### Learning

Using the paired feature vector and velocity estimate as training data, we can construct a  $k$ -NN which maps any new feature vector to the  $k$  most similar training instances and

Figure 3: Actuator model for *Notemigonus crysoleucas*

the associated observed motions. One interesting difference from the standard  $k$ -NN in this instance is that the output associated with each feature vector is a continuous set of values describing how the fish moved, rather than a discrete class. In the standard  $k$ -NN with discrete output, each of the  $k$  nearest neighbors to a given query  $q$  votes for one of the possible discrete outputs and the output with the highest number of votes is returned as the class for the query. We can generalize this by returning the output of an arbitrary function  $g$  of the  $k$  nearest neighbors for a given  $q$ :

$$f(q) = g(\{q_i \mid d(q_i, q) \leq d(q_j, q), \forall i < j, i = 1 \dots k\})$$

where  $d(q_i, q)$  is the distance between  $q$  and  $q_i$ . In the standard  $k$ -NN, the function  $g$  just returns the class with the maximum number of votes, or the mode of the classes of the  $k$  neighbors. Other choices for  $g$  include the mean, or median. Empirically, we've found that sampling randomly from the  $k$  neighbors works better than taking the mean. This might be due to the fact that the animals do not behave in a completely deterministic manner: In the case where the fish is approaching a wall head-on it may turn left or right to avoid it, but the average of both cases would be to head straight forward, leading to a collision with the wall. On the other hand, sampling randomly from the neighbors would produce both left and right turns, and in the proportion that they are represented in the data.

### Simulations of learned behavior

For our training set, we used tracking data collected from a 54 minute video of 30 *Notemigonus crysoleucas* schooling in a shallow tank 2.1 meters long by 1.2 meters wide<sup>1</sup>. From

<sup>1</sup>This data was one replicant from the experiments performed in Katz et al. (2011).

the tracks we computed the 13 features and 3 velocities described previously. The collected data amounted to roughly 2.6 million input/output pairs, which we used as training data for a  $k$ -NN. We constructed a simulation with 30 fish in a similar environment using BioSim, a freely available simulation toolkit<sup>2</sup>. At each time step, each fish computes the 13 features described earlier and sets its velocity by selecting from the  $k$  nearest neighbors. Figure 4 shows screenshots from the simulation and the resulting schooling behavior.

The fish are initially placed in the environment at random locations moderately spread out, but they quickly form into a single dense school. The school tends to stay close to the boundaries, tightly clustered. This is very similar to the behavior of the real fish in the training data, as shown in Figure 5.

As discussed in our motivation, one reason such agent-based simulations are useful is the ability to run experiments in simulation that would be difficult or time consuming to perform using live test animals. To illustrate this capability, we ran a simulation of 300 fish in a larger (3m by 5m) tank.

Figure 6 shows a screenshot of the 300 fish simulation. Notice how the fish have separated into several distinct schools.

## Conclusion and Future work

This work has illustrated how the process outlined initially can be applied to learn the schooling behavior of fish from video: by applying a standard multi-target tracking algorithm to video to produce tracks of position and orientation, then computing a set of input/output (features/motions) pairs from the tracking data, then using those pairs as training data for a learning algorithm ( $k$ -NN) to construct a mapping between observed features and agent output, and finally using that mapping as the basis for a simulation. Our experimental results show that the collective behavior of agents following the learned behavior is qualitatively similar to the schooling behavior which generated the training data.

It's important to note that the choice of algorithm for both the tracking and learning components are crucial. The noise inherent in the tracks produced by the tracking algorithm must be relatively small, otherwise the training data used by the learning algorithm may be so noisy as to not permit an accurate mapping. The tracking algorithm must also be able to account for all the variables of interest, such as orientation. The choice of learning algorithm also has a profound effect. In the case of schooling fish, it is apparent from flocking models that the collective schooling behavior can arise from purely local and *reactive* rules. In other words, the mapping we've discussed so far is *stateless* in that the output is dependent only on the observed features, and not any internal memory or state. However there are many interesting types of behavior that are not stateless in this sense,

such as foraging in ants (Yang et al., 2012) or the honey bee "waggle dance" (Oh et al., 2005). Learning these types of behaviors requires an algorithm that can handle state such as presented by Balch et al. (2006), and such algorithms are a focus of our current and future work.

## Acknowledgements

We would like to thank Iain Couzin and the Collective Animal Behavior lab at Princeton University for the use of their tracking data.

osawa@iit.tsukuba.ac.jp

## Abstract

Acquisition of the opponent's model and achieving mutual trust with others are notable traits of humankind's intelligence. Achieving mutual trust is a big challenge for artificial intelligences, and it is a key factor in trading. However, how players observe each others' behaviors and how they achieve mutual trust are not fully known. In this study, we researched the growth of a mutual trust protocol in a trading game in a human-based simulation. We designed and implemented web-based multi-player trading game based on the refusible iterative Anti-Max Prisoner's Dilemma game (rAMPD). In the game, each agent's strategy is described by an automaton and periodically modified by human players. We conducted a long-term human-based evolution of mutual trust using this trading game for approximately one month and observed how the agents' automata changed. Analyses of the high-ranking agents' automata and introspective reports by the human players revealed that the mutual trust protocol is achieved by using the initial trade as a signal for mutual recognition.

## Introduction

Intentional reading by an agent is an important topic in the field of artificial life. Learning the other's intention is called the Theory of Mind (ToM), and under the social brain hypothesis, it is thought to be a main factor in the evolution of our brains (Premack & Woodruff, 1978) (Byrne & Whiten, 1989). Being able to estimate the intentions of other people and trust them are important factors in trading in the real world and require intelligence. The "power of trust" becomes larger if an agent's reward is maximized or its penalty is minimized through trading; i.e., trading is encouraged when a winning agent gets a large reward and the losing one incurs only a small loss. Fisher and Shapiro used iterative arm wrestling for teaching the importance of trust in trading (Fisher & Shapiro, 2005). They demonstrated that if two players play an iterative arm wrestling game and the winner gets a reward in each match, it is better for both players to fix the game rather than engage in a real fight. They also showed that the key factors in agreeing to fix a game is that each player needs to be intelligent and trust that after if he or she intentionally loses a match, his or her opponent will intentionally lose the next match. They showed that mutual trust sometimes emerges even without words being exchanged between players.

The Iterative Prisoner's Dilemma (IPD) is a typical game in game theory, and it is designed in such a way that the reward is maximized if both players cooperate (Axelrod, 1984). A cooperative strategy in the IPD is achievable without players having to estimate each other's strategy. This kind of game model is appropriate for simulating ecological behaviors of animals that do not relate to ToM (Le & Boyd, 2007). On the other hand, it is insufficient for representing mutual trust in trading situations because mutual trust requires delayed actions. A human player can lose an arm wrestling match and still believe his or her opponent will lose in the next match.

The current study is on a human-based multi-agent simulation of a refusible iterative Anti-Max Prisoner's Dilemma game (rAMPD). It was conducted to see how mutual trust in trading arises. The Anti-Max Prisoner's Dilemma (AMPD) was first proposed by Angeline (Angeline, 1994). He modified the reward table of IPD so that it could cover the mutual trading behavior of Fisher and Shapiro's iterative arm-wrestling game. We included refusal as the third choice of the agent in AMPD (hence, refusible AMPD, or rAMPD). This extension can simulate real-world trading because each player has the right to ban opponents in free trade. We recruited 74 people to play the rAMPD in a simulation lasting 28 days, and the results of our analyses show how mutual trust arose during this game.

The following sections are organized as follows. Section 2 explains game rule of rAMPD. Section 3 explains how we implemented the system for human-based evolution and conducted experiments and the result of the experiment is shown in section 4. Section 5 analyzes the result and discusses how mutual trust and other strategies are acquired by agents. Section 6 describes how our result contributes to other research field and section 7 describes our method's limitation. Section 8 concludes the paper.

## Game Rules

Table 1 is the reward table of the trading game. The standard IPD conditions are shown in equation 1, and the AMPD conditions are shown in equation 2.

Table 1. Reward table of Trading Game

B \ A	Cooperate	Defect
Cooperate	$(A:c, B:c)$	$(A:a, B:b)$
Defect	$(A:b, B:a)$	$(A:d, B:d)$

$$a > c > d > b, \quad a + b < 2c \quad (1)$$

$$a > c > d > b, \quad a + b > 2c \quad (2)$$

We also added ‘refusal to trade’ as a choice for each agent. If the refusal is selected by an agent, the two agents finish their trade with no chance of retrying. We modified Axelrod’s reward table ( $a = 5, b = 0, c = 3, d = 1$ ) because it is commonly used in game theory simulations. To increase the value of refusal selection, we averaged four constants. We subtracted 3 from  $c$  and subtracted 2 from the remaining three. The reward table for rAMPD was thus ( $a = 3, b = -2, c = 0, d = -1$ ). The average of the four constants was 0, and this satisfied equation 2. The value  $c (=0)$  represents an example of Fisher and Shapiro’s arm wrestling that both player’s cooperative hands do not make sense.

In the rAMPD game, all agents traded with each other iteratively. We also selected the maximum matches in one trade up to 100 times. All agents traded in a round robin fashion. The round robin was repeated several times. The human participants could improve their agent’s strategy between each round robin.

## Human-based Evolution

### Notation of the strategy by automaton

Each participant got his/her own agent and input strategy of the agent through an automaton. We selected automaton-based description of strategy in three reasons. First, automaton-based strategy is understandable to participants especially who are not familiar about programming. Second, the automaton is easy to analyze because of its simple notation. Third, the automaton has enough describable for complex strategy.

Each participant input their agent’s strategy by using a finite state automaton. Each state in the automaton had numbers representing cooperation and defection of the agent. Even states represented cooperation, odd states represented defect, and 0 represented a refusal. The transition arrows between states were described with triplets numbers. The first number represents the present state, the second number represents the opponent’s hand (0 means cooperate and 1 means defect), and the third state represented the next state (even, odd, or 0 state). Each participant described their strategy using the start state number and several triplets. For example,  $\{2\}, \{2,0,2\}, \{2,1,2\}$  means a strategy that is anytime cooperative.  $\{1\}, \{1,0,1\}, \{1,1,0\}$  means coward exploiter. If it is once attacked, it refuses trade.  $\{2\}, \{2,0,2\}, \{2,1,1\}, \{1,0,2\}, \{1,1,1\}$  shows the strategy of tit-for-tat which is famous in IPD. We found that the finite state automaton made it easy for

players to understand each others’ behaviors, and that it is enough descriptive to maintain mutual trust.

### Implementation of the game: how to motivate participants

For motivating participants, we designed the simulation as an online game. All games were implemented in AJAX style, and participants input their strategies using a web form shown in Fig. 1. Each participant could download his/her agent’s trade history from the website at any time (shown in Fig. 1 top). The results of a trade were calculated on the server side and feedback to participants both ranking page and interactive result viewer. Each participant could replay their previous result in viewer mode (shown in Fig. 1 bottom).

Figure 1. Implemented game screen. Top figure shows the input form of the automation code of the text. Bottom figure shows the viewer mode. Both figures are captured from web browser.

We also wrote a cover story for the game to nurture the imagination of the participants and motivate their play. In the cover story, the participants were residents of an island, and they traded fish in a poisoned pond. Each fish became edible if it had been dipped in a different pond. Each agent could choose between three selections, to wait at home (C), to go to

an opponent's home and take fish (D), or to lock the door (refusal). If both agents wait at home, there was no reward and no penalty (0, 0). If both went the other's home, the doors were locked and both became tired (-1, -1). If one went to the opponent's home and the opponent was waiting there, he or she could eat the fish and the opponent lost it (+3, -2). If one of the players refused, the communication and trading stopped. This story is a bit artificial. However, every participant understands how the rule works.

## Participants

We conducted an experiment in a class learning about automata, and the participants were students from that class. In total, 74 participants played the game. The experimental period ran from 2012/5/29 12:30 to 2012/6/26 8:30. Trading was conducted four times a day during breaks between classes (8:30, 12:30, 16:30, and 20:30), and the ranking table was updated during this period. The chances for updates totaled 112 times. Because updates were done during breaks, each participant had enough time to input strategies and confirm the update's result before and after trading.

All participants were given scores for their class work according to their ranking at the end of the simulation. We divided up the participants who took more than 1 point into 16 groups (these agents were survivors which ate fish and were not hungry). Each group member got from 20 points to 5 points in order to his/her agent's score. The rules were described to the participants before the game started.

It was important for us to confirm that there were no ethical problems in conducting this experiment as a part of the automaton class because it was designed as both an experiment and as a means for students to learning the basic behaviors of automata. The experiment also included an evaluation of the students.

## Results

There were 1109 updates of the automata. The average number of update accesses per trade was 9.9. The average number of updates per player was 15 times. 68 agents achieved more than 1 point at the time of the last update, and their programmers were given bonus points in the class. According to their acquired score, we named each agent in order of highest score A01 to lowest score A74, categorized the 68 participants whose agents exceeded 1 into groups 20 (G20) to 5 (G5), and put 6 participants with less than 0 points in group 0 (G0). The average length of the agents' automata was 33.7. The average length of automata with more than 1 point was 36.5. Figure 2 shows the average length of automaton and average points in each group.

We categorized each player's state using the following rules. If both players each got more than 40 points and less than 60 points, we considered that both players trusted each other and categorized them into the mutual trust (MT) group. If one of the players got more than 50 points and the other got less than -50 points, we considered that one of the players exploited (EX) the other player and that other player was exploited

(EXd). If both players got less than -50 points, we considered that both players could not trust each other and mutual destruction (MD) occurred. If both players got less than 10 points and trading was stopped by one of the players, the trading was banned (BA). If both players got less than 10 points and trading continued until the end of the simulation, trading resulted in stagflation (ST). All categories are shown in Fig. 3. ST only happened in the lower-rank group G0. There are trends on Fig. 3 that higher-ranked agents achieve more mutual-trust than lower-ranked agents (note that BA in high-ranked agents are still required to prevent lower-ranked agents' attacks).

Figure 2. Average states of automaton and average points for each group. The right axis shows the number of automaton states, and the left axis shows the average number of points. The bottom axis shows the 17 groups.

Figure 3. Average number of categories in each group. The bottom axis shows the 17 groups.

## Discussion

### The General strategy of the high-ranked agent

Figure 4 shows a strategy of the high-ranked agent as a meta automaton. All high-ranked agents (in the G20, G19, and G18 groups) had four phases of their strategy. First, the agent repeated cooperate or defect in a determined order. This determined order was different in each agent. If the opponent selected a different hand, the agent transited to the mutual trust phase. In the mutual trust phase, the agent tried to take a complementary hand. If the opponent selected C continuously, the agent transited to the exploiting phase and tried to exploit the opponent. On the other hand, if the agent detected D continuously, the agent transited to the refusal phase and finished the trade

The detailed transition rules depended on the agent. Note that in this game, two identical automata do not succeed because they cannot change to different hands. This restriction discourages users from cheating and accelerates the evolution of the identification process.

From the participants' reports, we confirmed that participants gradually came to understand the several dilemmas in this game. For example, if the identification process is too strict (using lots of confirmation before mutual trust), the opponent may regard that it is impossible to cooperate and simply refuse the trade. This loses the chance of possible cooperation. However, if the identification is too loose, the opponent may think that the agent is too foolish to cooperate and start to exploit it. This also loses the chance to cooperate and reduces rewards.

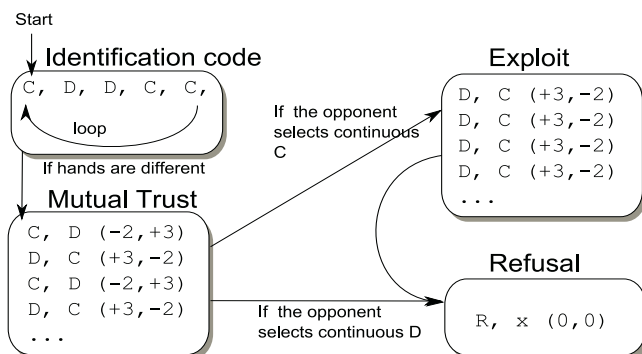

Figure 4. Example of strategy in high-ranked agent (the identification code is extracted from A02)

We studied the results of these three methods by conducting a statistical analysis, manual analysis (where the author input hands manually, traded with each agent, and observed the behaviors), and collecting reports from the participants. The next subsection discusses the analyses conducted during each phase.

### Identification Code Phase

We confirmed that at least 30 agents (A01-A30) had an identification code phase of manual analysis and the participants' reports. Each agent in 30 agents has a different set of hands on the start process (CDDCC, DCDC, etc.). If each agent's hand is different, they start to go mutual trust phase.

The length of the identification code loop was less than five pairs (For example, A02 had 5 loops and A04 had 3 loops). Theoretically, a  $2^5$  bit unique code is required to identify 32 agents. This result corresponds to the fact that the agents that had identification phases numbered less than 30.

57 participants selected D as the first hand of the agent and 17 participants selected C. Most participants selected D because the agent had a chance to get a higher score than the opponent. On the other hand, the participants who selected C reported that selecting C in the first hand had an advantage because it was easier to start up a mutual trust situation with it than D. One of the participants reported that his strategy followed an old proverb "win by losing."

### Mutual trust phase

Theoretically, mutual trust arises in a longer loop, like CCDD, CCCDD, etc. However, all agents used short mutual trust loops (CDCDCD...). 42 agents (A01-A41 and A61) had mutual trust phases. As shown in Fig. 3, high-rank agents had more mutual trust (MT) and fewer refusals (BA). This result suggests that lower-rank agents lost the chance through their own or their opponent's (BA) refusal, whereas high-ranked agents could use the chance to make a mutual trust loop (MT). A larger set of states in an automaton weakly suggests that mutual trust requires each automaton to have more complex states. This result suggests the validity of the social brain hypothesis wherein evolution of intelligence (approximated by the number of states) is accelerated through identification in society (Byrne & Whiten, 1989).

### Exploiting Phase

The exploiting phase was observed in almost all agents (A01-A71). There were 4 exploited agents (A71-74, all agents were in G0). Continuous Cs was a trigger for transiting to the exploiting phase. We confirmed that all agents who had an exploiting phase transited to the exploiting phase after 2 to 4 continuous Cs. As shown in Fig. 3, almost all agents attacked during the transit from the exploiting phase to the refusal phase.

Keeping the exploiting phase has a risk in that it may imprudently trigger the opponent's refusal phase. However, the exploiting phase was preserved until the end of the game because there are big rewards for exploiting phase. There were three participants who input only C regardless of their opponent's hand and did not change strategies (A72-A74). A71 had a simple strategy that selected a CCDDCCD... loop unrelated for the opponents' hands. These weak agents kept being exploited.

## Refusal Phase

The refusal phase was inevitable because if the opponent selected continuous D regardless of its hand, the agent prevented a negative score just by selecting refusal (C,D and D,D are both negative). 41 agents had a refusal phase (A01-A41).

All of these agents reacted to more than 3 continuous Ds. On the other hand, several agents allowed 1 or 2 Ds. These behaviors kept the opponent cooperative and not "be anger" (for triggering opponent's refusal attitude).

## Difference between rAMPD and AMPD

Each agent acquired more complex strategy in rAMPD compared with a strategy in AMPD game proposed by Angeline (Angeline, 1994). There are three factors for generating different results from previous research.

The first factor is difference of simulation. Angeline uses computer-based simulation for evolving each agent's strategy. On the contrary, we used human-based simulation. The latter condition expands the possibility of each agent's strategy. The second factor is the description of the strategy. Angeline uses set of four hands (CCCC-DDDD) for describing strategy of each agent. On the other hand, we used automaton for describing strategy. The automaton makes it possible to use more complex strategy. The third factor is the refusal hand of each agent. Refusal phase creates "point of no return" in each trade and it makes communication complex. In Angeline's AMPD game, each agent has no refusal selection and a trade continues to determined cycle. If an opponent plays continue Ds (which means two or more continued D hand), most appropriate strategy is replying with continuous D. If the opponent stops continuous D, the agent just needs to stop continuous D. In our situation, a most appropriate hand for the opponent's continuous D is just refusal. However, if continuous D are produced mistakenly by the opponent, there is still a chance for creating mutual trust in each other. We hypothesized that the refusal phase is the critical factor for evolving complex communication between agents. As a future work, we will confirm the hypothesis by using computer-based simulation.

## Contributions

We tried a human-based multi-agent simulation instead of a computer-based one. The human-guided approach is used in several fields, from artificial life, cloud sourcing, and human interfaces (Kosorukoff, n.d.)(Paolacci et al., 2010)(Osawa & Imai, 2012). Our results suggest that this approach also works if the motivations of the human players are carefully designed.

Our findings revealed two important factors related to game theory and multi-agent simulation. The first is in regard to the emergence of mutual trust in trading itself. In game theory, the possibility of mutual trading can be analyzed in the Cheap Talk Game that divides a trading game into an initialization phase and a main trading phase (Wärneryd, 1991). Our results suggested that identification of others and mutual cooperation can be achieved even without "cheap talk" by using the reward

itself. This finding may lead to multi-agent simulations becoming simpler as far as their requirements go. The second factor is the importance of being able to refuse during free trade. Previous studies mainly focused on the locality of the agent as a way of avoiding agents they were not confident about and this leads to agents forming clusters (Suzuki & Arita, 2001). This approach is good for ecological simulations. However, general free trade is not dependent on the distance to the others, but rather on the mutual intention of trading. Our results suggest that agents come to believe each other and reject agents they are not confident about not by using additional information (like cheap talk and location) but rather through behaviors.

In light of the above discussion, we think that our human-based multi-agent simulation of the rAMPD game reflected the essence of real-world free trading and gave us good insights about how identification of others and mutual trust arises in humans.

Last, we want to note that human-based multi-agent simulation quickly proceeds analysis for the game space because we can collect agent's process of evolution by participants' introspections. We want to emphasize that most participants are motivated by this gamification method (students involved in our "homework" make good scores in class). We believe that motivated participants are very good research factors for estimating the possibility of game space especially in earlier stages of study.

## Limitations

Human-based simulations are dependent on capricious humans. To handle human resources properly, we need to design the experimental setup carefully.

Although there were 112 updates in this task, almost all of them happened during the first week and final week. To maintain motivation during the whole game period, we may need to back-reward the participants (for example, by scoring on a weekly basis).

Three participants did not update their agents, and this sabotage influenced the other participants. Several participants complained in the report that the authors did not evict these three agents. We think that these variable motivations also reflected a real simulation. However, this result also shows the importance of a good motivation design in human-based multi-agent simulation. This underscores the need to carefully design the agent's goal - each participant's motivation - in a human-based multi-agent simulation.

Knowing the number of trades may increase the unwanted factors. The top scoring groups (G20 and G19) had more than 100 states in their automata. The analyses of the automata and the reports from the participants showed that a large number of states were prepared for the 100th match. Defect or refusal is the optimal strategy even if mutual trust arises because the 100th match does not have a succeeding match. There were also three agents that prepared the 100th match in G11, G14 and G16, as the spikes in Fig. 1 show. The reward (<5 points) for defect or refusal in the 100th match was relatively small

compared with the points from MT (around 50 points) and EX (around 300 points). The main ranking seemed dependent on the amount of mutual trust and the 100th match did not influence mutual trust. The increasing trend in MT in going from G10 to G20 (Fig. 2) supports this idea. These unwanted evolutions can be avoided if the number of matches is indefinite in each update.

Human-based simulations sometimes encounter ethical problems. For example, we could not regulate communications between participants, unlike in the case of a computer based multi-agent simulation. In this experiment, the participants were rivals and there was no real motivation to cooperate. Moreover, cloning was meaningless in this task. These two facts restricted communication between participants. The participant reports also suggested that there was no cooperation between the participants. However, it is hard to monitor the sorts of strategy that could have been generated through discussions with other participants. This problem may be avoided if the game is conducted online anonymously and all behaviors are monitored. Anyway, the experimenter must be careful about regulating human behaviors. It is important to ensure that the experiment is profitable for the participants themselves.

## Conclusion

We designed and implemented a web-based multi-player trading game based on the refutable iterative Anti-Max Prisoner's Dilemma game (rAMPD). In this game, each agent's strategy is described by an automaton and is periodically modified by human players. We conducted a one-month human-based multi-agent simulation using this trading game lasting approximately one month and observed how the agents' automata changed. Analyses of high-ranking agents' automata and introspective reports from the human players revealed that a mutual trust protocol arises using the initial trade as a signal for mutual recognition.

# Hebbian Learning In A Multimodal Environment

Julien Hubert, Eiko Matsuda and Takashi Ikegami

The University of Tokyo, Ikegami Laboratory, Tokyo, Japan  
 {jhubert,eiko,ikeg}@sacral.c.u-tokyo.ac.jp

## Abstract

Hebbian learning is a classical non-supervised learning algorithm used in neural networks. Its particularity is to transcribe the correlations between couple of neurons within their connecting synapse. From this idea, we created a robotic task where 2 sensory modalities indicate the same target in order to find out if a neural network equipped with Hebbian learning could naturally exploit the relation between those modalities. Another question we explored is the difference in terms of learning between a feedforward neural network(FNN) and spiking neural network(SNN). Our results indicate that a FNN can partially exploit the relation between the modalities and the task when receiving a feedback from a teacher. We also found out that a SNN could not complete the task because of the nature of the Hebbian learning modeled.

## Introduction

One important aspect of our everyday life is our capacity to acquire knowledge by experiencing our environment. Animals possessing the capacity to learn can detect and exploit the correlations present in their environment. This gives them, among other advantages, the capacity to predict their world and avoid undesirable outcomes, which is akin to Friston's free energy theory where living systems try to minimize their free-energy in order to increase their capacity of prediction of their environment(Friston (2010)).

The neurobiology of learning in the brain is driven by synaptic plasticity, also referred to as Hebbian plasticity or Hebbian learning after Donald Hebb who first proposed a theory of how learning could take place(Hebb (1949)). The general idea drawn from Hebbian learning states that when 2 neurons are connected together by a synapse, the correlated activity between the two would evoke structural modifications within the synapse such the capacity of the pre-synaptic neuron to cause potentiation in the post-synaptic one would increase(see Abbott and Nelson (2000) for a complete introduction). This phenomenon was observed at the neuronal level by Kelso et al. (1986).

The task we are interested in is a multi sensory integration task where a robot must reach a target indicated by a sound and a light source. The main question we want to address

is if a neural network equipped with Hebbian learning can naturally extract and exploit the correlation between the two sources. Indeed, sound and light are two sensory modalities with different properties and different yield. It would then be interesting to know if Hebbian learning has the potential of integrating them transparently, that is without any external mechanism for this task. It is generally expected that Hebbian learning can detect correlations at the neuronal level, but our question is if it can also integrate the correlations present in the environment in order to convey additional properties or abilities to its host. For instance, in this particular task, we are interested in the robustness that Hebbian learning can provide when noise is added on the sensors. Another aspect we explore is the effects of asynchronous activation of the sensory modules on the behaviour of the robot. The particularity of our experiment is that no mechanism helping the integration of the two sensory modalities is provided, and any emergent property of the system can only be the result of the Hebbian learning.

As a side experiment, we were also interested in the comparison between classical rate based neural networks and spiking based neural networks when it comes to Hebbian learning. Spiking neural networks(SNN) are a relatively recent paradigm where information transferred between neurons is no longer a continuous value, but a temporally limited event representing a neuron discharging its membrane potential (Maass (1997)). SNNs represent a model closer to the neurobiology of the brain, and as such possess also a model of Hebbian learning directly drawn from neurophysiological recordings. The particularity of this learning is that it incorporates a window of time where a synapse can be modified, which differs from the Hebbian learning used in classical NN where the changes are instantaneous. Our question is whether this architecture would lead to different behaviors. We will see that SNNs could not reproduce the behavior obtained by the traditional neural network, and we will discuss the causes and the impact of this result.

The article is divided in 3 sections. The first presents the experimental setup and includes a description of the task and of the controllers. In the second section are presented the

results for both controllers which are discussed in the last section.

## Experimental Setup

### The Task

Our experiments use a robot whose task is to move toward a target area in its environment. The robot moves in an open environment where one light source and one sound source are located at the same position. Facing those sources is a grid of 7x7 cells (see figure 1). Those are used as starting positions for the robot. The task of the robot is to navigate its environment using its sensors until it reaches a point at a maximum distance of 1 grid cell from the sources. The robot has 6 minutes to complete this task. If the robot reaches the goal within that time period, the trial is considered a success; otherwise, the trial is counted as a failure.

The robot and its environment are simulated in all the experiments. The simulation of the robot is based on the e-puck robot equipped with light and sound sensors (Mondada et al. (2009)). The simulation of the environment is based on data obtained from a real robot in a real environment. A model of the light and of the sound has been built using sensor readings gathered from a robot moving in the environment. This has consequences on the simulated sensors. The simulated light sensor can not perceive the emitted light from the source outside of its field of view. The simulated sound sensor does not only perceive the sound from the source, but also the sound from the motors of the robot. The noise generated by the motors can be louder than the emitted sound, preventing the robot from perceiving it. The real source of the light is a white neon bulb while the real sound source emits white noise. Figures 2 and 3 show respectively the light and the sound perceived by the robot at the different positions in the grid, the goal being located at coordinates (3.5, 7) on the graphs, i.e. at the center column of the top row. The frequency of update of the simulation depends on the neural network. In the case of the feedforward neural network, a timestep of 0.05s is used. For the spiking neural network, a timestep of 0.001s is used.

The performance of the robot is measured by its capacity to reach the goal in less than 6 minutes. For a single trial, the performance of a robot would be one if it reached the goal and zero otherwise. The duration of the trial is not considered in the performance measure.

### The Controller

As mentioned in the introduction, two controllers are tested in this task. The first one is a standard feedforward neural network (FNN). The second is a spiking neural network (SNN). Both are equipped with plastic synapses following a Hebbian rule. The number of input, hidden and output neurons remains the same with both controllers. The next subsection describes the implementation using the feedforward network. The differences with the spiking neural

Figure 1: Experimental arena. Each cell of the grid is a possible starting position for the robot.

Figure 2: Robot's perception of the light.

network will be explained later on. The next section will detail the FNN.

**Feedforward Neural Network** The FNN possesses 7 inputs and 4 outputs. No hidden neurons are present. The input and output layers are fully interconnected. The weights are tuned using Hebbian learning (Hebb (1949)). A visualization of the network is shown in figure 4.

The inputs of the FNN are divided into two groups. The first group is composed of 4 inputs and handles the perception of the sound. The second group contains 3 inputs and receives the perception of the light. In both cases, the inputs are not the outputs of the sensors, but a pre-processed version. Each sensor is connected to a memory containing the past readings of each sensor. In the case of the sound, the size of the memory is 30 readings. For the light, it is only 10 readings. The difference in memory size can be ex-

Figure 3: Robot's perception of the sound.

plained by the difference in noise between the two sources. The data from the sound sensor shows a higher level of noise while the light sensor shows a more gradual increase. This difference will become important when explaining how the inputs are computed. The light sensor also possess a single value memory updated every 120 timesteps and containing a single reading. We will refer to it as *imprint* later on. This imprint serves as an ambient light measure used by the controller to discriminate the light coming from the source.

Figure 4: Network composed of 7 input neurons(top) and 4 output neurons(bottom). The lines represent the synapses. The colors used represent the ideal connections between nodes. For instance, both red inputs should be ideally connected to the red output.

The controller described below has been first designed on a real robot and then transposed to simulation. Because the noise in a real environment differs from a simulated one, this approach guarantees that the behavior in simulation remains

the same as in reality.

**Inputs Pre-Processing** The inputs of the FNN are pre-processed in order to obtain binary inputs. The pre-processing is necessary for the Hebbian learning to be stable and is different for each type of sensor. Only one input can be activated for each sensor at every timestep. Practically this means that among the 7 inputs, 1 input from the first 4 and 1 input from the last 3 can be activated simultaneously.

The following equations describe the activation rule for the first 4 inputs relating to the sound perception:

$$I_0 = 1 \quad \text{if} \quad S(t) > S(t - 30) + 0.03 \quad (1)$$

$$I_1 = 1 \quad \text{if} \quad S(t) < S(t - 30) + 0.03 \quad (2)$$

$$I_2 = 1 \quad \text{if} \quad S(t) \geq S(t - 30) \quad (3)$$

$$I_3 = 1 \quad \text{if} \quad S(t) \leq S(t - 30) \quad (4)$$

where  $I$  are the inputs and  $S(t)$  refers to the sound sensor reading at time  $t$ . Those equations are evaluated in order and the evaluation stops when one input is set to 1.

The inputs relating to the light sensor follow a set of rules also. Before deciding which input to activate, the imprint must be subtracted from every reading used. The following equations describe the activation rule the last 3 inputs relating to the light perception:

$$I_6 = 1 \quad \text{if} \quad L(t) < 0.01 \quad (5)$$

$$I_5 = 1 \quad \text{if} \quad \begin{cases} L(t) < L(t - 10) - 0.01 \\ \text{the robot goes backward} \end{cases} \quad (6)$$

$$I_6 = 1 \quad \text{if} \quad \begin{cases} L(t) < L(t - 10) - 0.01 \\ \text{the robot goes forward} \end{cases} \quad (7)$$

$$I_5 = 1 \quad \text{if} \quad \text{if the robot goes backward} \quad (8)$$

$$I_4 = 1 \quad \text{if} \quad \text{if the robot goes forward} \quad (9)$$

where  $I$  are the inputs and  $L(t)$  refers to the light sensor reading at time  $t$ . As for the sound, those equations are evaluated in order and the evaluation stops when one input is set to 1.

The equations for the sound and the light sensors differ because of the properties of the sensors. For the sound, equations 1 and 2 target cases when the current level of sound differs from the past by more than a threshold. Equations 3 and 4 are used when the current level is below this threshold. For the light, equation 5 is applied when the light has no significant differences from the ambient light. Equations 6 and 7 deals with the case where the current level of light is lower than 10 readings ago. Finally equations 8 and 9 are used when there is no important change in the current light level. For the light, the direction of movement of the robot had to be taken into account as the sensor is directional.

The parameters used in the above equations were determined experimentally for our setup.

**Outputs** The outputs are squashed to a range of  $[0; 1]$  using the sigmoid function and are used to activate specific behaviors. Each output is attached to one behavior through a winner-takes-all strategy, i.e. the output with the highest activation activates its corresponding behavior. The four behaviors are:

1. Output 0 maintains the current behavior.
2. Output 1 inverts the current behavior. If the robot is going forward, it will go backward at the next timestep and vice-versa.
3. Output 2 modifies the current behavior to create a left turn while maintaining the same direction.
4. Output 3 modifies the current behavior to create a right turn while inverting the current direction.

**Learning** As mentioned previously, the weights of the FNN are tuned through learning using Oja's Hebbian rule (Oja (1982)). The rationale behind this choice is to allow the possibility for different couplings between the different sensory modalities. Despite the unsupervised nature of Hebbian learning, we cannot expect that the FNN will learn the task without supervision. For that purpose, we implemented a crude controller that will indicate which output should be activated based on the activated inputs. Once the FNN's outputs have been read and a behavior activated, those are replaced by the outputs advised by the teacher. It is possible that 2 outputs be activated at the same time as the light inputs does not necessarily indicate the same behavior as the sound inputs. In that case, two outputs are activated with a strength of 0.5. If both set of inputs concur on one behavior, its assigned output will receive an activation of 1. This will express the certainty of the decision of the teacher and influence the learning. Once the outputs have been modified, the Hebbian rule is applied and the weights are modified. The taught connections between inputs and outputs are as follows:

- Output 0 should be connected to input 0 and input 4
- Output 1 should be connected to input 1 and input 5
- Output 2 should be connected to input 2 and input 6
- Output 3 should be connected to input 3

Those ideal connections are also shown in figure 4, where inputs and outputs sharing similar colors should be ideally connected by the synapse of the same color.

**Spiking Neural Network** The SNN is based on Izhikevich neurons (Izhikevich (2003, 2004)). Contrary to feedforward neurons who possess a membrane potential that is continuous and transferred directly to other neurons, a spiking neuron transfers information in the form of spike. A spike

is an electrical impulse sent by a pre-synaptic neuron to all its post-synaptic neurons. The synaptic plasticity follows the model of STDP proposed by Song et al. (2000). This model differs from Oja's Hebbian rule used for the FNN as it incorporates a time window during which 2 spiking events will produce a synaptic modification. In other words, the firing of the pre- and post-synaptic neuron does not have to be simultaneous to produce a synaptic modification. The temporal sequence of firing is nevertheless important. If the pre-synaptic neuron fires before the post-synaptic one, the synaptic strength is reinforced. In the opposite case, the synapse is weakened.

The Izhikevich neurons are determined by 4 parameters. The values we chose to use correspond to the regular spiking model ( $a = 0.02$ ,  $b = 0.2$ ,  $c = -65mV$  and  $d = 6$ ). The parameters for the STDP are  $A_+ = 0.02$ ,  $A_- = 0.021$ ,  $\tau_+ = \tau_- = 0.02$ . For the SNN to be mathematically stable, the time step of the simulation has been increased to 0.001s. All the timings of the simulation have been adapted to reflect this change and to provide the same setup with the SNN than with the FNN.

## Results

### Feed Forward Controller

Using the FNN as controller, the robot manages to reach the target from all positions within the grid. The average success rate from every starting point in the grid, over 1000 repetitions, is shown in figure 5, where the target is located on the middle top position in the arena. The 3 graphs show the success for 3 different conditions. In the top left graph, the light sensor is the only one activated which gives us an idea of its usefulness to reach the target. It is interesting to notice that our robot appears to be better at picking the light coming from its right, as the performance is higher on the left side of the arena. The top right graph shows the success when only the sound sensor is activated. We can see that the performance is not symmetrical but is much more regular over the whole arena than for the light sensor. Nevertheless, the overall performance is lower. Finally, the bottom graph shows the performance when both sensors are activated. The pattern is similar to when only the sound sensor is activated, but we can notice a faster decrease in performance when far away from the target. We can also notice a slight tendency to have a higher performance when the robot is starting from the left side of the arena, which is consistent with what we see when only the light sensors is activated. As such, it is clear that both sensors influence the performance of the robot, but it is also clear that it is not always a positive reinforcement. It seems that both sensors interfere with each other at the level of the controller.

To explore how the sensors are combined by the controller, we performed an experiment where light processing and sound processing can possess different timescales, i.e. each one can be activated independently and at different tim-

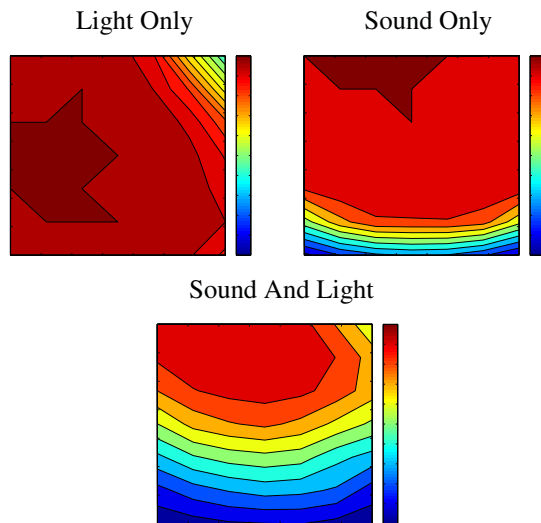

Figure 5: Rate of success for every starting cell within the arena, under 3 conditions: light sensor activated, sound sensor activated, both sensors activated. The goal is located on top central point.

ings. Also, we explored how sensory noise can influence the performance of the robot and if the plastic controller could compensate one sensor by the other. For all experiments, the level of noise describes the max value drawn from a uniform distribution that can be added to a reading of a sensor. The results are shown in figure 6. The left row shows the performance when noise is added to the sound sensor, while the right shows the same with the light sensor. Each row shows a different level of noise for their respective sensor. From top to bottom, the level of noise is increased by increment of 0.2. The X and Y axis provide the speed of update of the sensors. 1 means that it is updated every time step, while 20 means every 20 time steps. The X-axis provides the update speed of the light sensor, while the Y-axis the speed for the sound sensor. The Z-axis is the success rate.

When noise is applied, we notice that the performance is the same for any update speed, except when both modules function at the same speed. In that particular situation, the performance drops slightly, creating a ridge, which could be the consequence of an interference between the two sensory modules. When progressively adding noise, a drop in performance on one side of the ridge appears, but the other side is relatively not affected. The drop on one side only is the consequence of the difference in update speed of the 2 modules. When the noisy module is updated faster than the non-noisy one, this module drives the behavior of the robot more frequently. This is due to the fact that the commands of the noisy module will overwrite the decisions of the other one, as it is activated more frequently. As such, the robot makes more errors as it relies mainly on less reliable information.

When the faster module is the non-noisy one, it can compensate for the errors of the other module, reducing the impact of the noise on the system. We can nevertheless notice that in the area surrounding the ridge, the performance is higher even if the noisy module is updated slightly faster than the other one, which means that both modules are nonetheless interacting and improving the performance of the robot under noise.

Our last test is about the importance of each sensory module in the decision process. As the leading behavior is based on a winner-takes-all strategy at the level of the outputs, it is possible to compute which module takes the decision by observing which input produced the activation in the winning output. Figure 7 shows the rate of dominance of the light module, of the sound module, and the rate of cooperation between the 2 modules for different levels of noise applied on the sound sensor. The graphs show for any cell in the grid the percentage that the light or sound module decides the behavior for that particular cell. The cooperation rate is the percentage of time where the two modules agree.

We can see that the light module is the most dominant over all cells. The sound module has a maximum rate of decision of maybe 20%, while the light module can go up to 80%. This can be expected as the light is the most reliable sensor of the two. The most interesting aspect is how the rates change with the addition of noise on the sound sensor. From 0 to 0.5, we can see that the light module is now dominant over the all arena. This means that the sound being unreliable, it is barely used to drive the behavior. There is also almost no cooperation between the two modules. The sound module becomes relevant only when the robot approaches the sound source, probably because the light sensor at this position becomes saturated and a noisy sound sensor provides more information.

Additionally, we also plotted the average success rate for each condition with a varying level of noise, which can be seen on figure 8. As can be expected, when the light module is only active, the performance remains the same as it is not applied noise to. One visible aspect is that the performance with the sound module slightly increases initially, to decrease after a pick in terms of noise. This is due to the controller having been initially implemented in a real robot where the sound sensors delivered more noise readings. Consequently, our simulated controller performs better under a weak level of noise, which allows it to escape local minima within the sound landscape. Also, we can see that the performance of the sound only condition is initially higher than for the sound & light condition. But this changes above a noise level of approximately 0.2. This implies that the controller can support higher noise levels when both modules are activated.

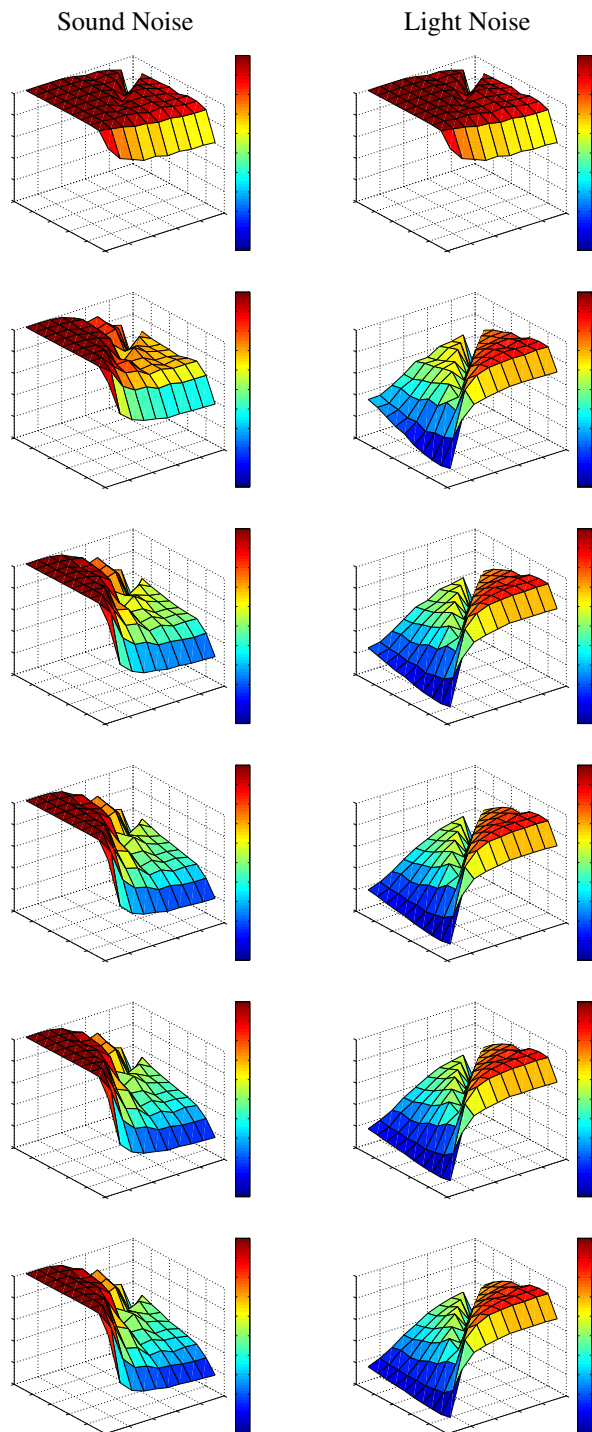

Figure 6: Variation of the performance of the robot under different timescales and different level of noise for the sensory modules. From top to bottom, the level of uniform noise is varied from 0 to 1 by increment of 0.2. The left column has noise on the sound sensor only, while the right one has noise on the light sensor only.

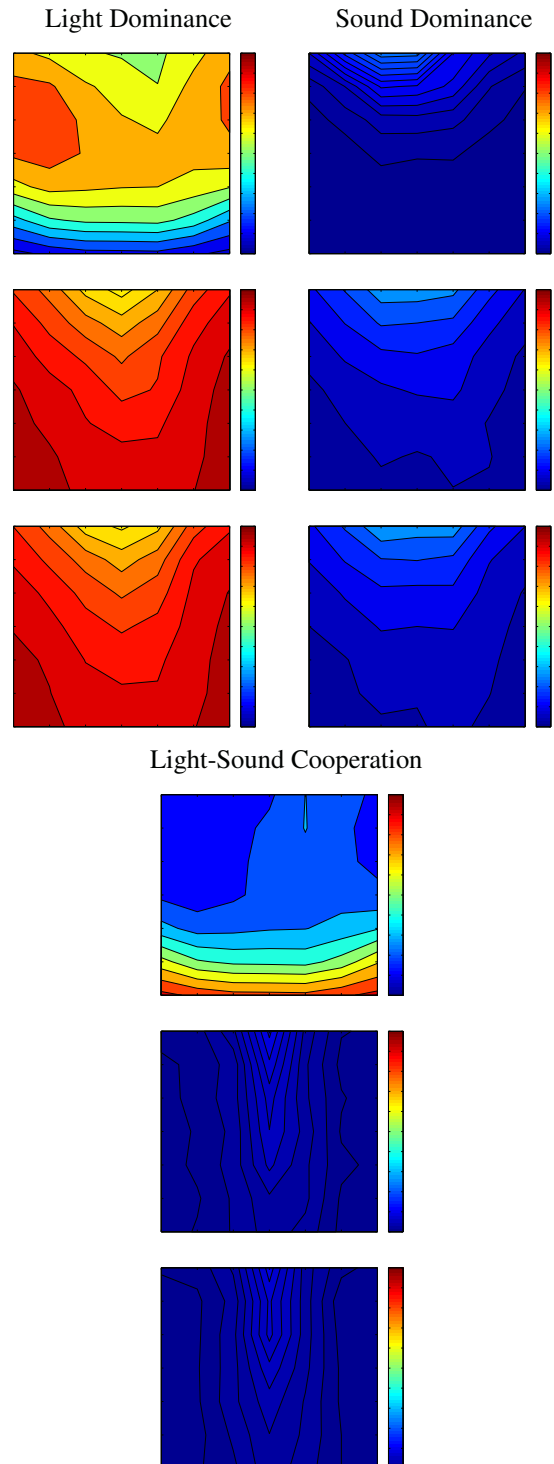

Figure 7: Rate of dominance and of cooperation between the light and sound modules for 3 levels of noise applied on the sound sensor: 0, 0.5 and 1.0.

Figure 8: Comparison between the performance of each condition (light only, sound only and both) with different levels of noise on the sound module.

### Spiking Controller

The results with the FFN were interesting so we expected a lot from the SNN. Unfortunately, despite many attempts, we were unable to reproduce the results obtained earlier. The SNN was not capable of extracting the right connectivity from the correlations present in the environment. Fortunately, the reason is quite clear and can shed some lights on the differences between using a FFN and a SNN, and can help orient the design of robotic experiments using a spiking controller.

The reason for the lack of replication of the task can be found in the window of time during which synapses are modified under STDP. This window is roughly 40ms where a synaptic strength can be either reduced or increased. In our case, the problem comes from alternating behaviors. Following what we described previously, input 0 would ideally be connected with output 0, and input 1 to output 1. As the inputs are never activated simultaneously, and the learning chooses a winner-take-all strategy on the outputs, the FFN obtains the right connection as the computation of the change in synaptic strength has no memory of the past activation of the neurons. In the case of STDP, such a memory exists. If two behaviors alternate frequently, and are separated by less than 40 ms, they will interfere with each other and create synaptic connections that should not have been learned. For instance, if input 0 spikes, then we would want output 0 to spike also later on. If this is the case, their connecting synapse is strengthened. If soon after, input 1 spikes, followed by output 1. Then, not only their connecting synapse will be strengthened, but also the synapse connecting input 0 and output 1. Over time, the activation of input 0 will create an activation in output 0 and output 1. This is equivalent to learning the wrong correlations from the environment.

At this point we need to mention that a SNN can of course resolve this task, but it would need a different architecture as the one we offer here. It would need one that can cope with the interferences. Our search for different parameters for the SNN, or by changing some details of the task, did not lead to a successful learning. Our next step should be to research what kind of topology can cope with the interferences. This might imply introducing some kind of modularity in the system.

### Conclusion

At the beginning of the article, we wanted to explore two questions. The first was if a neural network equipped with Hebbian learning could naturally learn and exploit the correlations present in an environment where a target is indicated by two sensory modalities. The second was if there was a difference between a feed forward neural network and a spiking neural network, both equipped with their version of Hebbian learning, in terms of performance on the task. We can start answering those two questions.

Concerning the first question, it is difficult to say that Hebbian learning was sufficient to learn the correlations in the environment. Figure 5 and 8 show that the controller displays a different behavior when the light and sound modalities are provided, compared to the situation when only one of them is used. This tells us that the network is exploiting both sensory modalities, and that the combination is not a simple linear sum of both modules. Furthermore, the dominance analyses shown in figure 7 confirm that based on the amount of noise on one modality, the less noisy one becomes more important in deciding which behavior to activate. This supports the idea that Hebbian learning, combined with a teacher, could naturally exploit the most reliable information present in the environment. The teacher is important because he guarantees that the most reliable connections between inputs and outputs are more frequently reinforced compared to the more noisy ones. Following that idea, it becomes also plausible that Hebbian learning could modify the connectivity of the network to promote one sensory information if it provides the most reliable information within a specific area in the robot's environment. Without the teacher's feedback, it seems difficult for the Hebbian learning to naturally exploit this information. Indeed, deactivating it does not lead to a successful behavior. But through the teacher's interaction, the system managed to rely on the most reliable sensor to complete the task.

The answer to the second question is that there are clearly some differences between Hebbian learning in FFN and SNN. The interferences between the different behaviors prevent the network to learn the relevant correlations from the environment. This clearly demonstrates that there are important differences between the classical Hebbian learning found in FFN and the STDP found in SNN. The time window used by STDP to compute the synaptic modifications

are responsible for the failure to learn our particular task. As this mechanism has been modeled directly from real synapses going through strengthening or depression, ignoring this difference might lead to undesirable effects. For instance, the conclusions drawn from a robotic experiment using FFN and Hebbian learning might not be related to what could be happening in a real neural network because time has not been taken into consideration. As one goal of artificial life is to understand life as it is by recreating it, it might be wise to work with closer models of the brain in order to draw conclusions relevant to what we are interested in.

# Follow the Leader: a Scalable Approach for Realistic Group Behavior of Roaming NPCs in MMO Games

Dario Maggiorini, Laura Anna Ripamonti, Samuele Panzeri

Department of Computer Science, University of Milano, Italy  
 ripamonti@di.unimi.it

## Abstract

In modern Massively Multiplayer Online Games, Non Playing Characters (NPCs) moving on the battlefield play a key role in term of user experience: many time players are required – alone or in groups – to fight or avoid them in order to progress in experience. Unfortunately, standard NPCs behavior, i.e., patrolling between rally points, does not put a significant challenge to players once its deterministic movement pattern is discovered. This paper addresses the problem of defining a smart, more challenging, and natural movement model for NPCs. Getting inspiration from the kids’ game “follow the leader” we adopt Artificial Intelligence techniques such as behavior trees and blackboards to provide NPCs with changing paths, dynamic aggregation in parties, and tactical decisions. Following this approach, players’ experience will greatly improve thanks to an always-changing battlefield scenario.

## 1 Introduction

In these recent years, with the gain in popularity of online games, and massive online games in particular, we are witnessing a progressive increment in the number of Massively Multiplayer Online Games (MMOGs) available over the Internet, as reported by (MMORPG community). A MMOG is a multiplayer game where a huge number of users in a shared virtual environment can interact in real time and band together to achieve shared goal such as conquering a map or defeating a group of monsters. When designing the environment, Non Playing Characters (NPCs) are the most common interaction points between players and the game system. NPCs are autonomous entities in the virtual world in charge of assigning tasks (quests) to players or to oppose players when they are trying to fulfill quests. In particular, mobs (shorthand for “mobiles”) are NPCs roaming the map and typically implement monsters to be defeated or avoided.

In standard implementations, due to technical and computational constraints, mobs (alone or in groups) patrol between pre-defined rally points on a map. This way, it is easy to keep mobs density uniform on the map and level designers may be reasonably sure about not having unguarded passages through a battlefield. Moreover, this standard approach is not very computational intensive and allows for a better scalability. Nevertheless, mobs moving between fixed rally points are not very entertaining for players (Koster, 2004): fixed paths can be easily guessed by experienced players and free passages in the battlefield will be discovered eventually. To address this issue, we believe that Artificial Intelligence

(AI) techniques can be exploited in order to provide a better user experience. By using AI, it is possible to model every mob as an independent agent; each agent may be able to randomly choose its own path while coordinating with others to keep mobs density constant.

This paper focuses on proposing and implementing a novel movement model for mobs inside an MMOG. NPCs will benefit from changing paths, dynamic aggregation in parties, and tactical decisions. The proposed solution will make gameplay more challenging and entertaining for players by providing always-changing battlefield scenarios.

The rest of this paper is organized as follows: first we discuss issues related to implementation of smart NPCs in Sec. 2; then, in Sec. 3, related work in literature is presented. The proposed solution is introduced and discussed in Sec. 4 while Sec. 5 provides details about our prototype implementation. Finally, Sec. 6 concludes the paper.

## 2 Artificial Intelligence and MMOGs

Artificial Intelligence has been present in videogames starting from the late 70s. Among the first examples we can find Qwak (Atari, 1974) and Pursuit (Atari, 1980). Pac-Man (Midwest Games, 1980) is the first notable example where the opponents, controlled by AI, follow distinct - and personalized - behaviors. Starting from Pac-Man, it become commonplace to include an AI subsystem in every game engine.

Videogame implementations up to a few years ago saw every agent as an independent entity taking autonomous decisions. This design was mainly due to the limited computational power available, constraining agents to very simple behaviors. In the majority of cases, NPCs were designed to just go toward or away from the player. Nevertheless, thanks to a new technology wave in the past decade, complex decision making techniques have been introduced in videogames. These decision making techniques allow for tactical coordination between agents with a significant increase in realism. Unfortunately, this same evolution is yet to come in MMOGs where the extremely high number of players and NPCs poses serious scalability limitations; World of Warcraft (Blizzard, 2004), as an example, reports 11.1 millions active users as of today.

When implementing an online game, one of the most important factors for player experience is the frame rate (Frame Per Second, FPS), which is the rate used to update the

game status on client side. A good, and constant, FPS value (typically between 30 and 60) provides a reactive game with smooth visuals. A reduction of FPS due to workload will lead to variable interaction times and unpredictable lags in the world evolution. In an MMOG, the update of the virtual world status is performed in a centralized way: a game server will take care to compute the new world configuration and distribute it through the network to all clients. To reach 30 FPS on every client, we are required to solve all interactions between users (and NPCs) at least once every 33 ms at server side. As a result, the number of NPCs and the complexity of their behavior is technically limited by the server computational power. Since the number of agents to simulate in an MMOG is at least two orders of magnitude greater than a single player game, AI solutions commonly used in standalone games becomes technically useless; game designers are then required to choose between few smart NPCs (in a small world) or many dumb ones (on a larger map).

Due to the above limitations, mobs' behavior in a MMOG follows a very simple model: every agents can assume two states: idle and in combat. When in idle state, the mob patrols between pre-defined rally points. If the mob is in combat state, it moves toward the player in a straight line and, when it gets close enough, starts attacking. The transition between these two states is triggered by the player's avatar being in or out the field of view of the mob. Usually, there is very little (if any) coordination between NPCs converging on the same player.

### 3 Related Work

Despite the fact that the problem we are addressing in this paper is of obvious interest for MMOG service providers, it seems, to the best of our knowledge, that limited efforts have been devoted to this topic from the scientific community. We may hint to two reasons for this situation: the tremendous expansion of online gaming is a relatively recent phenomenon, and commercial MMOG engines are usually secretly kept by the running companies making it very difficult for researchers to perform experiments. We believe that in the future, with the increasing popularity of open-engine MMOGs such as PlaneShift (Atomic Blue, 2000), the situation will positively change.

Most probably, the first work on the topic is (Reynolds, 1987). In this paper, the author proposes a computer model for a coordinated animal motion such as bird flocks and fish schools. These generic simulated flocking creatures have been baptized *boids*. While boids are actually providing a realistic behavior, they are missing any sort of group management: all agents in the simulation always move as a single flock.

In some more recent studies, such as (Synnaeve, 2010) and (Rhujittawiwat, 2006), AI techniques are applied to NPCs mainly to create a more believable behavior during combat. In (Synnaeve, 2010) authors use Bayesian programming to select actions and pick targets in a battlefield where both allies and foes are present while in (Rhujittawiwat, 2006) a genetic algorithm is used as a learning method to train an NPC about how to assist real players. None of these contributions are set on the specific goal to bound the computational workload on

servers and improve scalability. Moreover, both papers use simulated environments for performance analysis instead of real game engines.

Other works, such as (Combs, 2005) and (Fairclough, 2003), focus on using AI to improve storytelling. In particular, in (Fairclough, 2003) a character director system, which dynamically generates and controls a story, is proposed. In both cases, authors focus on storyline quality and completeness; limited attention is devoted to real-time interaction and system performances.

Most probably, the most interesting contribution on the topic comes from Zyda et al (Zyda, 2010a; Zyda 2010b). In these works, authors propose Cosmopolis: a free MMOG for larger-scale social modeling. In this virtual world, AI-driven NPC communities featuring customized cultural models are used as a means of researching interactions between individuals and societies. Despite some similarity in the goals, it is difficult to compare Cosmopolis and our work. This is because Cosmopolis is strictly focused on interaction and designed specifically as a research testbed for social and behavioral models while, in this paper, we propose an approach to be implemented in existing game engines to reduce computational workload on servers.

## 4 The Proposed Solution

In this section we are going to describe our solution to make mobs' movement and behavior more realistic in MMOGs.

To design our model we took inspiration from the kids' game "follow the leader". In this game a kid is elected as the leader and is free to move and behave as she likes; other participants are supposed to follow and mimic her, anyone who doesn't follow exactly is out of the game. Kids, during play, may also decide to join as followers or leave the group as they like.

We envision a MMOG where mobs move using a random path selection and are able to band together and perform coordinated actions. Every mob will wander randomly until another mob – or a group of mobs – will be in its field of view; when this happens, the wandering mob can decide to join to the mob/group and become a follower. In those cases where two mobs will band together, one of them will be elected leader and made responsible for group steering. Periodically, every member of the group may decide to leave and go back wandering alone; when the leader leaves the group another one will be elected.

From a technical point of view, the group may be considered as a stand-alone agent whose code sits on the leader; the group will be identified by means of a reference point (group position) and an orientation (see Fig. 1).

Following this approach, we can use a smart – and complex – behavior to manage the whole group while keeping the followers from using excessive computational resources. Resources request from the followers may get even lower than the standard approach thanks to the reduced number of decisions they will be required to take. Player experience, on the other hand, will benefit from many improvements:

- leaders (groups) paths may now be selected randomly to raise the bar in term of offered challenge;

Figure 1: A group seen as a single agent with a leader and followers inside.

- players will feel the mobs as more realistic by seeing them moving in platoons;
- a group will be able to take tactical decisions based on a strategic assessment of player capabilities (i.e., to flee or to fight).

#### 4.1 Movement

The group movement, i.e., picking direction and speed for the group, will be in charge to the leader.

Many strategies are possible for path selection; e.g., we can choose a random rally point, pick a steering angle every frame, or head toward (or away from) other mobs or a point on the map. The implementation of these movement algorithms strictly depends on the kind of mobs we are going to model; as said, doing this at group level allows us to push on complexity without overloading the system. As long as the paths are not pre-determined our model will work and we are not going to discuss algorithms for path selection here.

The first real issue we are going to address is how to make all mobs move in a coordinated formation. As already explained, the leader will set a pace and all followers will do the same while trying to keep a certain distribution pattern. How the pattern is selected is also up to the kind of mobs we are going to model; as an example, if mobs are soldiers an ordered formation is preferred while if they are wild animals picking random positions around a center point might be a good solution.

A more important decision than selecting a distribution pattern is about choosing how group movement should be implemented. We have two options: one- and two-level formation steering. With one-level steering the pattern is fixed and the whole group moves as a single unit keeping rigid distances between followers. This solution is easier to implement but fitting the pattern in the environment (e.g., a pack of wolves traversing a forest) may become a problem. With two levels we have to provide a formation manager to process the pattern and assign destinations to followers (i.e., wolves will swerve around trees and go slightly out of formation but will also try to stay close to the ordered position). This second option is preferable because mobs will blend more nicely within the environment. Moreover, the additional computational requirement for individual

movements is, in total, usually less than what is required to fit the formation pattern in the environment.

To implement the two-level group movement we define a center point for the group (which might not be the physical location of the leader). Group collisions and line of sight may be calculated starting from this center point; this way, computation will not be required for every group member and having a global line of sight/hitbox will still be valid approximation. Mobs take relative positions around the center point following the required pattern and, on every frame calculation, a proper destination is assigned to each follower. All computation required from follower agents is a linear movement to location that is “close enough” to the current destination while avoiding environment obstacles.

#### 4.2 Group Management

The group management deals with members joining and leaving the group and how single actions are coordinated between group members. The most viable way to perform these operations is by means of a decision making process.

Implementing a decision making process in every group member is not an easy task. A first option could be to use a Finite-State Machine (FSM). A FSM is a mathematical model of computation used to design systems that can be in one of a finite number of states. The machine is in only one state at a time and can change from one state to another by a triggering event or condition. A FSM-based approach could be too demanding in term of memory and will require state changes depending on the state of other members, with severe scalability reduction. A second option could be to adopt Hierarchical FSM (HFSM), where the states can be ordinary states or super-states, which are FSM themselves. HFSM may be a better solution but they are not always granted to provide satisfactory performance. For the above reasons, we decided to adopt Behavior Trees (BTs) for group management. BTs are a formal, graphical modelling language used primarily in systems and software engineering; they employ a well-defined notation to unambiguously represent a large number of natural

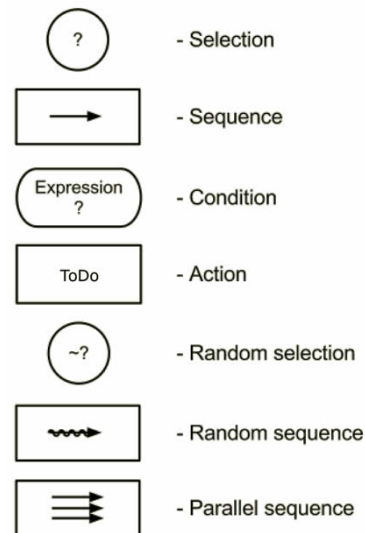

Figure 2: Symbols used in Behavior Trees.

language requirements to express the stakeholder needs for a software-integrated system. Thanks to their structure, BTs also allow to hide a subset of the information shared between group members in action and condition nodes; this way, we can also limit the complexity added by followers dynamically joining and leaving the group. Figure 2 reports the symbols we will be using in our BT schemes.

Communication and coordination between group members is performed using a blackboard system. A blackboard system is not a decision making tool in its own rather than a mechanism for coordinating the actions of several decision makers. The basic structure of a blackboard system has three parts: a set of different decision makers (called experts), a shared memory area, and an arbiter. Any expert may use the shared memory area to read system status and write suggestions about actions to be undertaken. Permission to access the shared memory must be granted by the arbiter. In our specific case, the experts are the mobs and the group agent.

Since, as already discussed before, we can see the whole group as a single agent we need two coordination systems: one between mobs and one between each mob and the group agent. To achieve this we extended the general concept of blackboard to a multi-level blackboard. A multi-level blackboard is a blackboard with two memory areas, which will host both of the above coordination systems (see Fig. 3). The first memory area is used for coordination between mobs; this area allows coordinating and prioritizing actions of single group members, e.g., first attack using magic, then with long-range weapons, and then using melee combat. The group agent uses the second memory area to suggest decisions to all mobs based on group status or environment; e.g., if one of the members is under attack someone must cure it and others should fight back.

An open issue with this blackboard-based approach is how to implement an arbiter that is able to satisfy the timing requirements of an MMOG. To speed-up execution, it is possible, when the number of experts is low, to remove the arbiter and use BTs where one or more nodes are tagged using states and priority values. During execution, first the group agent and then the other mob agents run their decision process. Once the group agent has run to completion it will write on the blackboard the selected action with its associated state and priority. After the group agent is done, all mob

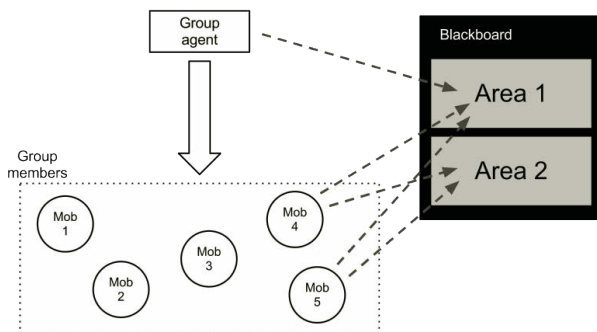

Figure 3: Scheme of a multi-level blackboard.

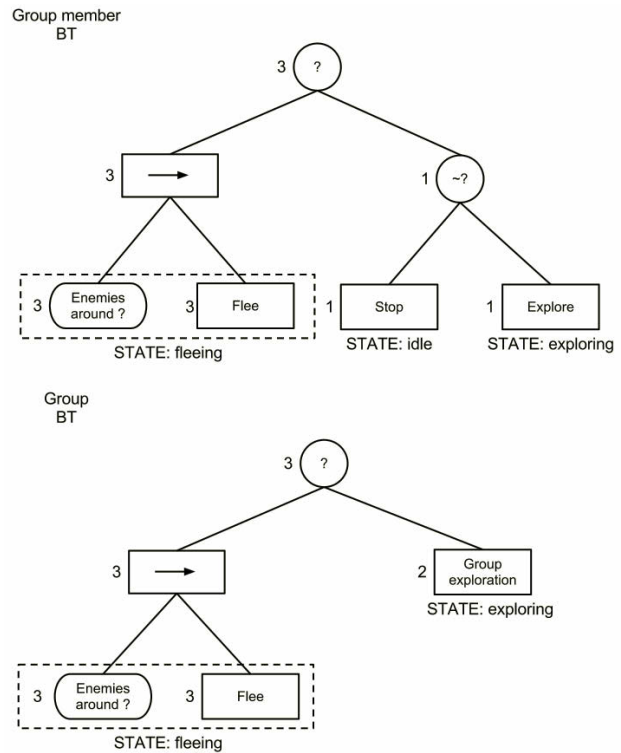

Figure 4: Sample Behavior Trees for an exploration group.

agents can start executing their own BTs. During execution, branches with a lower priority value than the one reported on the blackboard will not be evaluated. If, at the end of the execution a group member reaches a state with a higher priority than the one on the blackboard it will perform that action autonomously, otherwise (i.e., an untagged node has been reached or there is no execution with nodes on higher priority) it will perform the action selected by the group. In Fig. 4 a couple of sample BTs for an exploration group are shown. In the picture we can observe that explorers may act alone or in a group. In the case enemies are around the explorer will always flee. In the case no one is around it may decide to stay idle or to explore the surrounding, unless it is in a group; otherwise, it will be always required to explore with the other mobs (priority 2 on node “Group exploration”).

As we can see, following this approach it is easy to model complex behaviors for partially independent agents inside a group. Moreover, a single BT is able to describe both group and solo behavior for all mobs.

## 5 Prototype Implementation

In this section we are going to describe a prototype implementation of the system we presented in the previous section. This test application has been implemented using C++ and OpenGL.

In our prototype we define a square battlefield where a variable number of mobs and environment obstacles are randomly placed; see Fig. 5 for a screenshot. In the figure, the player's avatar is located in the lower right corner and the user can change its position using the keyboard. All other agents

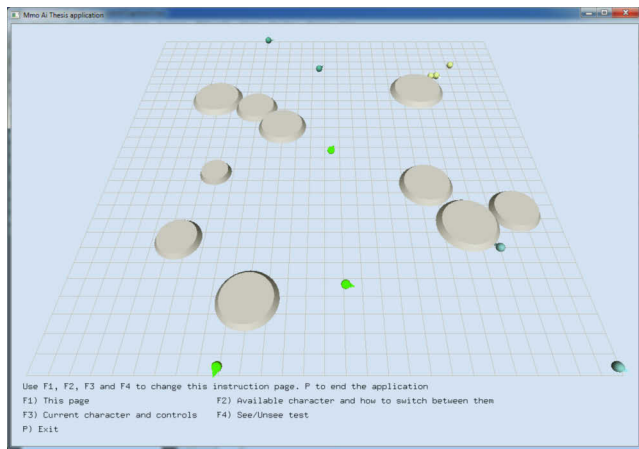

Figure 5: A screenshot of the prototype application.

are calculated in real time by our engine. To mimic an online game, the application implements two independent software modules (back-end and front-end) exchanging information via socket. The back-end works as a server taking care of AI execution for all agents and sending virtual world updates to the frontend. The front-end draws the virtual world on screen and implements the user interface. Using the front-end module the user can manipulate simulation parameters and move her avatar.

Mobs can be assigned to different groups (indicated by their color in the screenshot); only mobs belonging to the same group can band together. These groups are modeling different kind of monsters sharing the battlefield. Mobs will not attack each other.

When a group encounters the user's avatar a tactical decision is taken by the leader based on the group strength (the number of members): if the group size is below a certain threshold (i.e., it is weaker than the user) it will start to flee, otherwise it will start an attack. Since the combat system is not a key point at this stage of the project, attackers will just go toward the target and the defender is supposed to flee. During pursuit, the number of group members may change, because mobs can still join, leave, or are just left behind. On a group change, the tactical decision is re-taken and an attacking group may decide to just leave the player alone. If the player manages to leave behind a pursuing group, the mobs will start moving randomly again.

The purpose of environment obstacles is mainly to check the two-level implementation of group movement. They are currently implemented as circular “hills” to achieve easier collision detection based on distance.

## 5.1 Movement

Every group (and single mob) moves at a constant speed along its orientation. On every frame calculation a (small) steering angle is randomly selected taking collisions with hills into account. The group will move using an arrowhead formation (as in Fig. 1).

## 5.2 NPCs Behavior Tree

The BT used in mobs is depicted in Fig. 6. As we can see, the first branch is selected when the mob senses an enemy (or is under attack) or there is a help request from another mob nearby. If the mob is inside a group it will enter the “Notifying” state and write on the blackboard that an enemy is

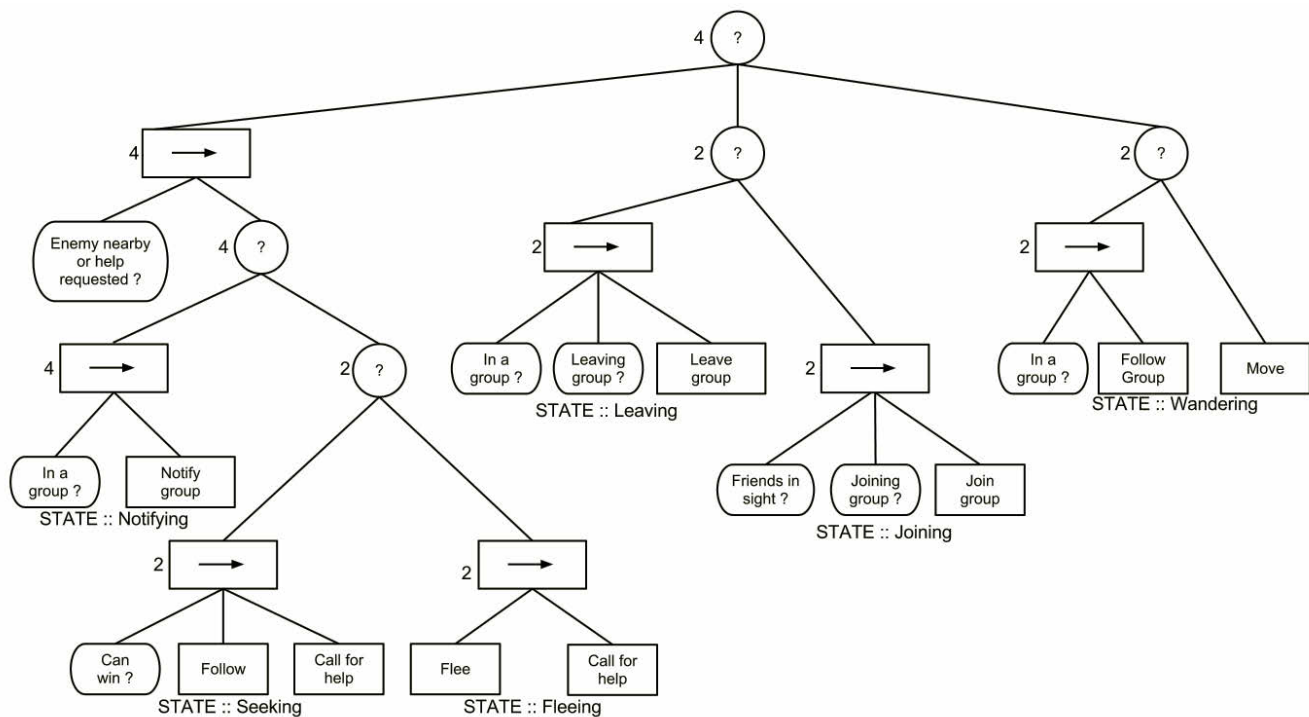

Figure 6: NPCs Behavior Tree in the prototype.

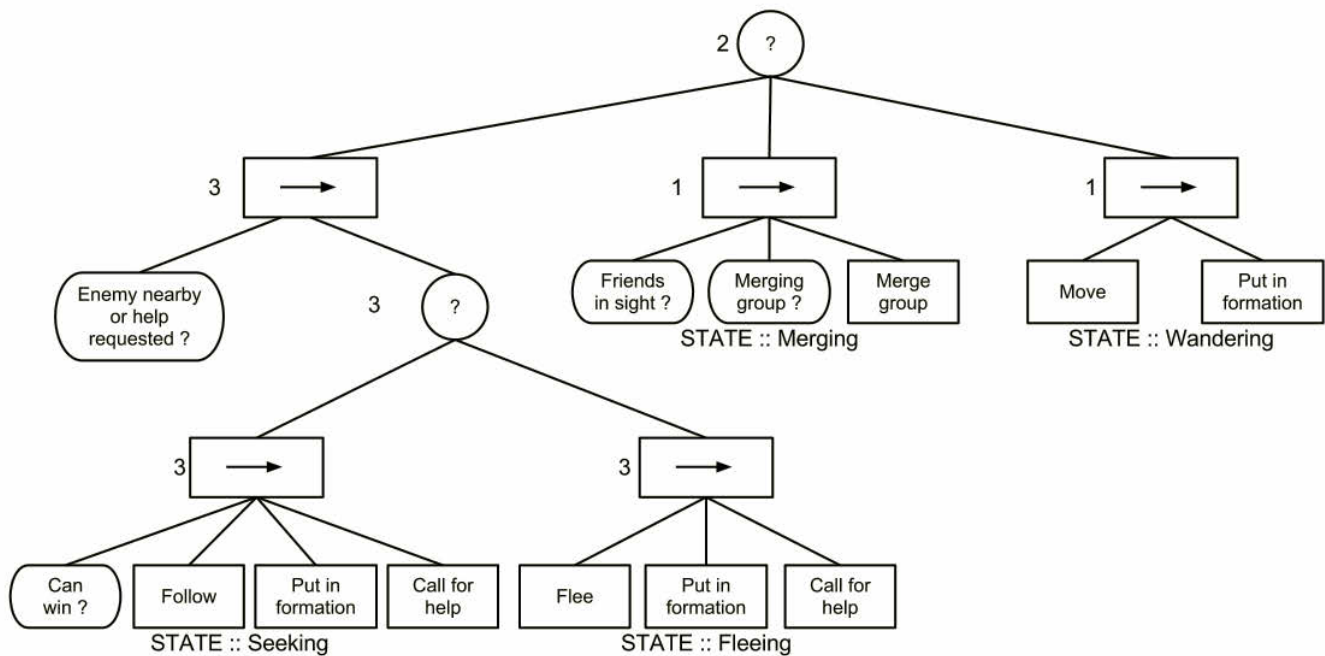

Figure 7: Group Behavior Tree in the prototype.

nearby and submit to the tactical decision that will be taken from the leader. Posting the message on the blackboard will also allow other group members to converge on the enemy even if it is not yet in their field of view. Otherwise, if the mob is not in a group, it must take its own tactical decision: fight or flee. If the mob evaluates it can win the battle it will start in pursuit (“Seeking” state) of the enemy, calling also for reinforcements. Otherwise, if the enemy is stronger, it will start to escape (“Fleeing” state) also calling for reinforcement and, eventually, to become stronger and fight back. The branch we just discussed will be evaluated also in the case the mob will hear a help request coming from another group (if it is from the same group, the blackboard takes precedence). When called for assistance, the mob will still need to take a tactical decision and evaluate if it is better to give support or flee.

The second branch of the behavior tree deals with group management. If the mob is in a group and wants to leave the state is set to “Leaving”; then, the mob will become an independent agent. Otherwise, if there are friendly units nearby and the mob wants to join the group, the state is set to “Joining”. The willingness of a mob to join or leave a group is evaluated with a random variable following a Bernoulli distribution where  $p$  can be set from the front-end interface (by default  $p=0.1$ ). In order to limit group dynamics we also set a minimum time  $t$  for the mob to stay in a group before leaving: only if enough time has passed the random variable can be evaluated. As for  $p$ ,  $t$  is set from the interface with a default value of 5 seconds.

The last branch is the one managing movement when no other mob is around (“Wandering” state). If the mob is part of a group it will just follow the leader (reading from the blackboard); otherwise, it will pick its own random steering angle and proceed along its orientation.

### 5.3 Group Behavior Tree

The BT used in groups is presented in Fig. 7. The first branch in the figure, as for the mobs, is selected when there are enemies around. Differently from the previous case, the group will not post on the blackboard but, rather, force a (global) strategic decision on all group members with priority 3. Single mobs will still notify other group members (priority 4) but will follow the strategic decision taken from the group agent, because that specific sub-branch has priority 2. When the tactical decision is taken from the group agent, the “Seeking” and “Fleeing” states also provide an action labeled “put in formation”. This action will make all group members rearrange around the group position; the actual location may change depending on the mob stance: attacking, fleeing, or just moving around.

The second branch manages group merging: if two groups are close to each other, one of the group agents may decide to merge and become one with the other. This state has no correspondence with the “Joining” and “Leaving” states of an NPC; since it has a lower priority compared to the second branch in Fig. 6, it is possible for a mob to leave a group independently from an ongoing merging action.

The last branch of the BT takes care of the group movement when no one is around: it sets the new group position (using the blackboard) and puts all participants into formation.

### 5.4 Testing the Architecture

During experiments the user moves on the battlefield and try to escape from the mobs after attracting their attention. Subjective evaluation of groups in pursuit gave positive results in term of movement patterns: formation seems to

adapt smoothly enough to the obstacles and server workload is reasonable. As a matter of fact, CPU usage never rose over 70%.

Increasing the number of mobs on the map requires more than 500 agents to drop performance below 30 FPS on a middle-end PC (Intel dual core at 2.5 GHz with 4 GB of main memory). Despite the fact that 500 agents are much less than the total population of an MMOG (which is in the order of millions, as claimed in Sec. 2), we have to remember that: (i) agents are managing NPC, which are outnumbered by players with at least two order of magnitude and (ii) the complete infrastructure of an MMOG provides a virtual world replicated on a number of independent clusters (realms) where each server in a cluster is in charge of a subsection of the local map. With the above considerations in mind, an acceptable workload with 500 agents is also an encouraging result. Nevertheless, the scenario is still hard to evaluate without an implementation inside an actual game engine.

## 6 Conclusion and Future Work

In this work we addressed the problem of realistic movement for Non Playing Character in Massively Multiplayer Online Games. Realistic behavior can be achieved adopting Artificial Intelligence techniques but, despite tremendous technical improvements in the last decade, application to massive environments is still critical due to performance constraints. We proposed a solution based on a hierarchical approach: NPC can aggregate in groups to be managed as a single agent; a group agent will impose general decisions (such as movement) to all members while single NPCs will manage simpler decisions (such as joining or leaving a group). The proposed solution has been used to implement a prototype. In our prototype NPCs populate a battlefield with environment obstacles; they roam the battlefield and eventually aggregate in groups to attack (or escape from) the user. First results are encouraging: NPCs behavior feels quite natural while server workload is bound to an acceptable level.

Future evolutions for this work include cooperation between heterogeneous NPCs, and the implementation inside a real game engine such as unity3d (Unity Technologies, 2005) or smartfox (gotoAndPlay(), 2004).

## Abstract

This paper investigates the evolution ability of Tierra-based Asynchronous Genetic Programming (TAGP) as GP using an *asynchronous* evaluation. We compare TAGP with two simple GP methods, steady-state GP and GP using  $(\mu + \lambda)$ -selection as GP using a *synchronous* evaluation. Three GP methods are compared in experiment to minimize the size of an actual assembly language program in several computational problems, two arithmetic and two boolean problems. The intensive comparisons have revealed the following implications: (1) TAGP has higher evolution ability than GP using synchronous evaluation, *i.e.*, TAGP can evolve smaller size programs which cannot be evolved by GPs using synchronous evaluation; and (2) the diversity of the programs evolved by TAGP can derive a high evolution ability in comparison with GP using synchronous evaluation.

## Introduction

*Evolutionary Algorithms (EAs)* like *Genetic Algorithm (GA)* (Goldberg, 1989) and *Genetic Programming (GP)* (Koza, 1992) requires the appropriate diversity of a population to evolve solutions efficiently. As approaches to such diversity, the conventional EAs focused on the genetic operators or selection strategies. For example, the adaptive parameter setting methods have been proposed to control a probability of the genetic operators depending on the fitness in the population (Subbu et al., 1998; Yun and Gen, 2003; Lin and Gen, 2009), or NSGA-II (Deb et al., 2002) which is well known multi-objective evolutionary algorithm (MOEA) employs an idea of the crowding distance which is based on the distance of solutions to maintain the diversity of solutions. Furthermore, EAs such as *Differential Evolution (DE)* (Storn and Price, 1997) and *MOEA/D* (Zhang and Li, 2007) which have recently attracted much attention on have a high evolution ability by evolving solutions independently, which contributes to maintaining appropriate diversity of solutions. Such an independent evolution is based on the *asynchronously* evaluation approach which evolves solutions asynchronously unlike the conventional EA approach which is based on the *synchronous* evaluation approach which evolves solutions

*synchronously*, *i.e.*, solutions are evolved by genetic operators after all individuals are evaluated. One main advantage of such *asynchronous evaluation* in EAs is to be able to derive the diversity of a population without any special heuristic operation.

This paper aims at verifying the evolution ability of the asynchronous evaluation on the program evolution. Since the previous asynchronous approaches such as DE and MOEA/D cannot be easily applied to the program evolution, this paper employs a novel GP method using the asynchronous evaluation, named as *Tierra-based Asynchronous Genetic Programming (TAGP)* (Nonami and Takadama, 2007; Harada et al., 2010, 2011) the previous researches proposed. TAGP is based on the idea of a biological evolution simulator, Tierra (Ray, 1991) and asynchronously evaluates and evolves programs. Since TAGP has the same advantage of the other EAs using asynchronous evaluation such as DE and MOEA/D, TAGP has a potential of evolving programs efficiently by maintaining the appropriate diversity of a population. To investigate such as evolution ability of TAGP, this paper compares TAGP as GP using the asynchronous evaluation, with two simple GP methods, steady-state GP (SSGP) (Reynolds, 1993) and GP using  $(\mu + \lambda)$ -selection  $((\mu + \lambda)$ -GP) as GP using the synchronous evaluation. The experiment applies these three GP methods to several computational problems to minimize the size of an actual assembly language program.

In the following section, we firstly explain a biological evolution simulator, Tierra, which ideas are employed in TAGP, and explains the algorithm of TAGP. Then we compares TAGP with SSGP and  $(\mu + \lambda)$ -GP in several computational problems, and gives its result and detailed analyses. Next section discusses the difference of three GP methods, and this paper finally gives conclusions and future works.

## Tierra

Tierra (Ray, 1991) proposed by T. S. Ray is a biological evolution simulator, where digital creatures are evolved through a cycle of a self-reproduction, deletion and genetic operators such as a crossover or a mutation. Digital creatures live

in a memory space corresponding to the nature land on the earth, and they are implemented by a linear structured computer program such as the assembly language to reproduce (copy) themselves to a vacant memory space. CPU time corresponding to energy like actual creatures is given to each creature, and they execute instructions of a self-reproduction program within allocated CPU time. Since given CPU time is shorter for execution time of programs, all programs are executed in parallel. Lifespan of a program is decided with a *reaper* mechanism. All programs are arranged in a queue, named as *reaper queue*, and a reproduced program is added to the end of the reaper queue. While program execution, a program that can correctly execute its instruction moves its position in the reaper queue to lower, while one that cannot correctly execute its instruction moves its position to upper. Then, when a memory space is filled, a program that is at a top of the reaper queue is deleted from the memory. Due to the reaper mechanism, programs that cannot reproduce themselves within allocated CPU time or include some incorrect instructions are deleted from the memory, while creatures that can reproduce themselves propagate in the memory.

As results of such evolution, Tierra generates, for example, programs, called *parasite*, that reproduce themselves by using other program's instructions, or ones, called *hyper-parasite*, that have immunity to the *parasites*. Note that this evolution is not pre-programmed in Tierra but is caused by *emergence* (Langton, 1989). As the final stage of Tierra, programs that have shorter program size or have efficient algorithm are generated, that require less CPU time than an initial program to reproduce themselves (ATR Evolutionary Systems Department, 1998).

## Tierra-based Asynchronous Genetic Programming

### Overview

The previous researches focus on the feature of Tierra which can evolve programs, *i.e.*, digital creatures, with asynchronous execution, and have proposed a novel GP based on Tierra mechanism, named as *Tierra-based Asynchronous Genetic Programming (TAGP)* (Nonami and Takadama, 2007; Harada et al., 2010, 2011). To apply Tierra to evolving programs with a given task, the previous research introduces *fitness* commonly used in EAs to evaluate programs, and also introduces reproduction and deletion mechanisms depending on *fitness* into Tierra. This is because it is impossible to give any purposes to programs in Tierra whose purpose is only to reproduce themselves.

Fig. 1 shows an image of TAGP. TAGP firstly starts from a program that completely accomplishes the given task. Programs that consist of a linear structured instructions and some registers are stored in a limited memory space. Each program executes a small number of instructions, which is

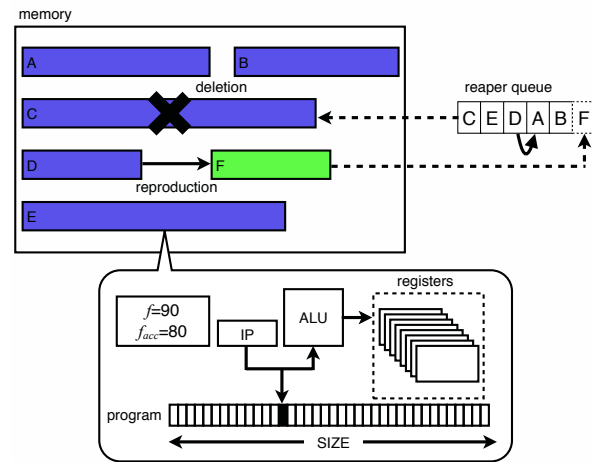

Figure 1: An image of TAGP

preconfigured, *e.g.*, three instructions, to simulate a parallel execution. All programs are arranged on *reaper queue* that controls lifespan of programs. When an execution of a program is finished, its fitness is evaluated depending on its execution result, and the reproduction and the reaper queue control are asynchronously conducted according to its fitness. When the memory is filled with programs, programs that are arranged at the upper of the reaper queue are removed from the memory.

### Algorithm

TAGP evolves programs through the following selection, reaper queue control, reproduction, and deletion algorithms. The algorithm of TAGP is shown in Algorithm 1 where 1,  $prog.f_{acc}$  and  $prog.f$  respectively indicate accumulated and evaluated fitness, and  $rand(0, 1)$  indicates random real value between 0 to 1.  $prog_{prev}$  indicates a previously selected program, while  $elite_{prev}$  indicates a previously selected *elite* program (detailed in below).

**Selection and reaper queue control** When an execution of one program is finished, its fitness is evaluated depending on its register value and the evaluated fitness is added to an *accumulated fitness*  $prog.f_{acc}$  (the 1<sup>st</sup> line in Algorithm 1). Based on  $prog.f_{acc}$ , whether a program is selected as a reproduction candidate or not is determined. Let represent the maximum fitness as  $f_{max}$ , if the accumulated fitness of a program exceeds  $f_{max}$ , it is selected as a reproduction candidate, and  $f_{max}$  is subtracted from its accumulated fitness (the 2<sup>nd</sup> and 3<sup>rd</sup> lines). While if not, a program is not selected. Depending on this selection condition, a program that completely accomplishes the given task, *i.e.*, its fitness is equal to  $f_{max}$ , is invariably selected because the accumulated fitness always exceeds  $f_{max}$ . High fitness programs have a high potential to be selected because the accumulated

**Algorithm 1** The algorithm of TAGP

---

```

1:  $prog.f_{acc} \leftarrow prog.f_{acc} + prog.f$ 
2: if  $prog.f_{acc} \geq f_{max}$  then
3:    $prog.f_{acc} \leftarrow prog.f_{acc} - f_{max}$ 
4:   repeat
5:     down reaper queue position
6:   until  $rand(0, 1) < P_{down}(prog.f)$ 
7:   reproduce better program of  $prog$  and  $prog_{prev}$  with
   genetic operators
8:    $prog_{prev} \leftarrow prog$ 
9:   if  $prog.f = f_{max}$  then
10:    if  $prog$  is better than  $elite_{prev}$  then
11:      reproduce  $prog$  without any genetic operators
12:    else
13:      reproduce  $prog$  with genetic operators
14:    end if
15:     $elite_{prev} \leftarrow prog$ 
16:  end if
17: else
18:   if  $rand(0, 1) < rand(\frac{prog.f}{f_{max}}, 1)$  then
19:     remove  $prog$  from memory
20:   end if
21:   repeat
22:     up reaper queue position
23:   until  $rand(0, 1) > P_{up}(prog.f)$ 
24: end if

```

---

fitness frequently exceeds  $f_{max}$ , while low fitness ones are hard to satisfy this condition.

Then, a position in the reaper queue of a program that satisfies the selection condition becomes lower than the current one, *i.e.*, its deletion probability decreases (the 4<sup>th</sup> ~ 6<sup>th</sup> lines), while one that does not satisfies the condition becomes upper, *i.e.*, its deletion probability increases (the 21<sup>st</sup> ~ 23<sup>rd</sup> lines). The move distance is determined by the move rate represented as  $P_{down}$  and  $P_{up}$  which are calculated as the following equation based on fitness,

$$P_{down}(f) = \frac{f}{f_{max}} \times P_r, \quad P_{up}(f) = \frac{f_{max} - f}{f_{max}} \times P_r, \quad (1)$$

where  $P_r$  is the maximum probability of  $P_{down}$  and  $P_{down}$ , which is preconfigured. Depending on these equations, higher fitness programs are arranged on lower position in the reaper queue, *i.e.*, survive long, while lower ones are arranged on upper, *i.e.*, are easily removed.

**Reproduction** Programs selected depending on the selection condition become a reproduction candidate. To reproduce better program asynchronously, TAGP only compares two programs, a currently selected program and a previously selected program described as  $prog_{prev}$  in Algorithm 1 and better one is selected as a parent. A selected program generates an offspring with the genetic operator such as a

crossover and a mutation, and an offspring is reproduced to a vacant memory space that is larger than its program size (the 7<sup>th</sup> ~ 8<sup>th</sup> lines). Additionally, the elite preserving strategy (Jong and Alan, 1975) is applied to preserve programs that can accomplish the given task (the 9<sup>th</sup> ~ 16<sup>th</sup> lines). If a current program is evaluated as  $f_{max}$ , it is compared with one that is previously evaluated as  $f_{max}$  represented as  $elite_{prev}$  in Algorithm 1. Then if the current one is better, it is reproduced as an elite program *without* the genetic operators to preserve better program, *i.e.*, generating a copy of the elite, while if not, it is reproduced *with* the genetic operators. TAGP employs four genetic operators, a crossover, a mutation, and an instruction insertion/deletion. The crossover operator combines a reproduced program with a previously selected parent. The mutation operator changes one random instruction in a reproduced program to other random instruction. The insertion operator inserts one random instruction into a reproduced program, while the deletion operator removes one instruction selected at random in a reproduced program.

**Deletion** TAGP conducts two deletion. One is a deletion based on the reaper queue that is conducted during the reproduction process. If a vacant memory space is not found when reproducing an offspring, programs that is arranged upper in the reaper queue are removed until a total vacant memory space becomes greater than a certain threshold, *e.g.*, usually set as 20% of the memory. This deletion remove elder and lower fitness program.

While another deletion is a *natural death* which is based on the idea of *sugarscape* (Epstein and Axtell, 1996). The natural death applied to programs that do not satisfied the selection condition according to the 18<sup>th</sup> ~ 20<sup>th</sup> line in Algorithm 1, where  $rand(a, 1)$  indicates random real value between  $a(\leq 1)$  to 1. This deletion removes lower fitness programs even if the memory is not filled.

## Experiment

To validate the evolution ability of TAGP, this paper compares TAGP with two simple GP methods, steady-state GP (SSGP) (Reynolds, 1993) and GP using  $(\mu + \lambda)$ -selection  $((\mu + \lambda)$ -GP), with four computational problems. SSGP and  $(\mu + \lambda)$ -GP are hereinafter collectively called SGPs (synchronous GPs). SSGP selects two parents from the population and generates two offspring, then the worst two programs in the population are replaced with generated offspring.  $(\mu + \lambda)$ -GP generates  $\lambda$  offspring from the population consisting of  $\mu$  programs, and leaves better  $\mu$  programs from  $(\mu + \lambda)$  programs to next generation, where  $\mu = \lambda$  in this experiment.

## Computational problems

This paper applies three GP methods to the following four computational problems shown in Table 1.

Table 1: Computational problems

Problem type	Function	# of training data
Arithmetic1	$x^4 + x^3 + x^2 + x$	16
Arithmetic2	$x^y$	25
Boolean2	6-multiplexer	64
Boolean2	5bits digital adder	32

Fitness is evaluated as

$$fitness = f_{max} - \frac{1}{n} \sum_{i=1}^n |\hat{y}_i - y_i|, \quad (2)$$

where  $f_{max}$  indicates the maximum fitness,  $n$  indicates the number of the training data,  $\hat{y}_i$  indicates the function value calculated from the  $i^{th}$  training data, while  $y_i$  indicates the output of a program in respect to the  $i^{th}$  input value. Note that when comparing the same fitness programs, the program size is firstly compared, and if is also equal to, the number of executed instructions to calculate all training data is finally compared.

This paper employs a program written by an actual assembly language embedded on PIC16 micro-controller unit (Microchip Technology Inc., 2007) developed by Microchip Technology Inc.. This is 12bits word assembly language, and has 33 simple instructions that consist of add-subtract, logical, bit, and branch instructions, but not contain a multiplication. One program can use 16 general 32-bits registers, named as  $R0$  to  $R15$ , and one temporary 32-bits register, named as  $W$ , while its size is limited to 256 instructions. The input value is firstly set from  $R1$  register, and other registers are initialized as 0. Note that since this instruction set does not include a multiplication instruction, programs have to combine some instructions and loop structures to calculate multiplication. Therefore, to calculate both of regression problems, programs have to include loop structures. Concretely, Arithmetic1 includes three multiplications ( $x^2$ ,  $x^3$ , and  $x^4$ ), while Arithmetic2 includes double multiplications loop to calculate  $x^y$  in both initial programs.

The experiment starts from an initial program that can completely solve the given task, and compares evolution ability of three GP methods by observing how small program can be obtained in one hour.

### Parameter settings

Common parameter settings for all three GP methods is shown in Table 2, ones for only SGPs is shown in Table 3, and ones for only TAGP is shown in Table 4. Three GP methods employ the same genetic operators, crossover, mutation, and instruction insertion and deletion, and also employ the same parameters for the crossover, mutation, insertion, and deletion rate. Only one genetic operator is executed with the configured probability for each reproduction. Crossover method is two point crossover, and the maximum

Table 2: Common parameter settings

Parameter	value
Crossover rate	0.7
Mutation rate	0.1
Insertion rate	0.1
Deletion rate	0.1
Crossover method	Two point crossover
$f_{max}$	100

Table 3: Parameter settings of SSGP and  $(\mu + \lambda)$ -GP

Parameter	value
Selection	Binary tournament
Upper execution steps	50000

Table 4: Parameter settings of TAGP

Parameter	value
Removing threshold	20% of memory
$P_r$	0.9

Table 5: Memory size of TAGP and population size of SSGP and  $(\mu + \lambda)$ -GP in each problem

Problem type	TAGP	SSGP	$(\mu + \lambda)$ -GP
Arithmetic1	6400	100	100
Arithmetic2	6400	200	50
Boolean1	25600	200	200
Boolean2	6400	50	200

fitness ( $f_{max}$ ) is set as 100. In SGPs, the binary tournament selection is employed, while the upper execution steps are restricted to 50,000 and if execution steps exceeds, its fitness becomes the minimum value. In TAGP, the deletion removes programs until the total vacant memory exceeds 20% of the memory size, while  $P_r$  is set as 0.9, which is the maximum probability of  $P_{down}$  and  $P_{up}$ .

Settings of population size of SGPs and memory size of TAGP is determined based on pre-experiment. SGPs compare results of 50, 100, and 200, while TAGP compares results of 6400, 12800, and 25600. Note that since the maximum program size is configured as 256 instructions, when the population size is set as 100, a used memory space of SGPs is equal to the memory size 25600(= 256 (instructions)  $\times$  100 (individuals)) of TAGP.

### Result

The experiment conducts 30 trials for three GP methods, and we evaluate three GP methods based on a percentage of trials in which a program for each size can be generated in one hour. Fig. 2 shows the result of a percentage of trials in which a program for each size can be generated in one hour. In Fig. 2, the abscissa indicates the program size, while the ordinate indicates the percentage of trials which can generate a program for each size. The red lines show the result

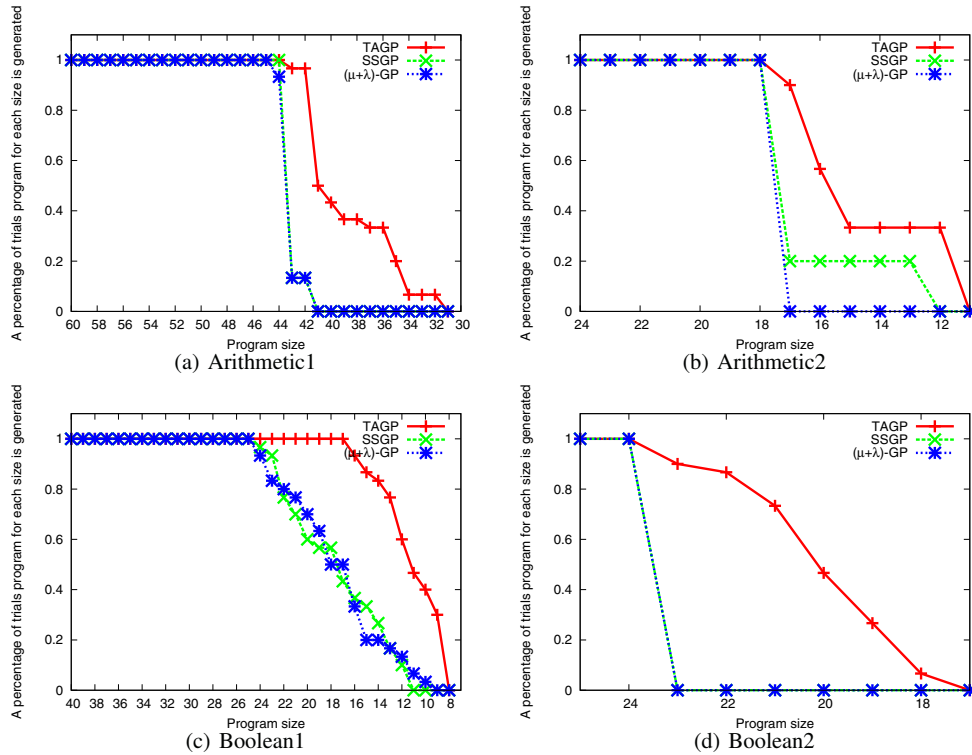

Figure 2: A percentage of trials in which a program for each size is generated in one hour

of TAGP, the green lines show the result of SSGP, while the blue lines show the result of  $(\mu + \lambda)$ -GP.

From Fig. 2, it is revealed that, in all computational problems, TAGP can generate smaller size programs than both of SGPs. Mann-Whitney U test is used to compare the generated program size of all GPs in all problems. The level of significance is set at  $\alpha = 0.05$ , and significant differences between TAGP and SGPs are verified. Focusing on the program size finally generated with each GP, programs of a certain size are generated with all GPs, concretely 44, 18, and 24 in Arithmetic1, Arithmetic2, and both of boolean problems respectively. It is, however, hard for SSGP and  $(\mu + \lambda)$ -GP to generate programs that size is smaller than the size described above. While TAGP can generate such programs in most trials.

To clarify the reason why TAGP outperforms SGPs, in the following, we analyze evolution processes observed in experiments. The evolution processes falls into two main categories, *non-destructive evolution* and *destructive evolution*. *Non-destructive evolution* means that it does not affect calculation result, *i.e.*, does not decrease fitness of a program, during evolution process, and is easily achieved. While *destructive evolution* means that it is required to decrease fitness of a program or to increase program size during evolution process. Non-destructive evolution also falls

into two categories, *single-step* and *multi-step*, the former means that it completes only single genetic operation, while the later means that it requires two or more genetic operations to complete its evolution process. Note that all destructive evolution is *multi-step* because it requires two or more genetic operations. The following sections describe details of these evolutions.

**Single-step non-destructive evolution** Single-step non-destructive evolution evolves programs by removing unnecessary instructions which do not affect the calculation result. As shown in Table 6, the problems except Boolean2 include some number of unnecessary instructions, and removing these instructions can decrease the program size. This evolution can be easily achieved because it can decrease the program size by not affecting the calculation result, *i.e.*, not decreasing fitness. Regarding Arithmetic1, Arithmetic2, and Boolean1, since programs that size is respectively 44, 18, and 36 are easily generated by only removing unnecessary instructions, all GPs accomplish 100% success rate, but one trial of  $(\mu + \lambda)$ -GP in Arithmetic1.

**Multi-step non-destructive evolution** Multi-step non-destructive evolution generates small size programs by replacing several instructions with one or a few instructions. Examples of observed evolutions are shown in Fig. 3. In

Table 6: The initial program size and the number of unnecessary instructions in each problem

Problem type	initial program size	# of unnecessary instructions
Arithmetic1	62	18
Arithmetic2	25	7
Boolean1	41	5
Boolean2	26	0

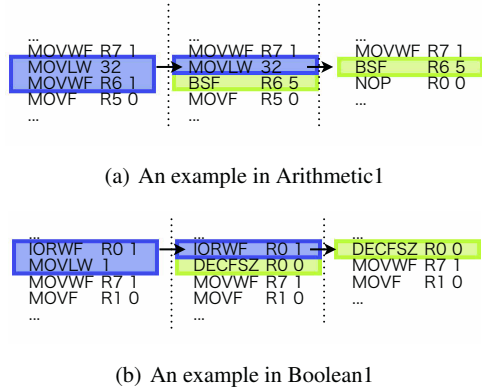

Figure 3: An example of multi-step non-destructive evolution

these figures, colored instructions are replaced with one instruction by using two genetic operations.

In Fig. 3, the left figure indicates a part of a program before evolutions, while the center and the right ones indicate the change of instructions. The colored instructions in the left figure substitutes a loop counter 32 to  $R6$  register through the temporary register  $W$ . This process requires two instructions, *MOVLW* which substitutes a literal to  $W$  register and *MOVWF* which substitutes the value of  $W$  register to any register. These two instructions are replaced with *BSF* which sets 1 to any one bit of any register. In this case *BSF* sets 1 to 5<sup>th</sup> bit of  $R6$  register. This works just as well as the previous two instructions, *i.e.*, sets 32 to  $R6$  register. While in Boolean1, a lot of examples are observed to replace logical instructions (*AND*, *OR*, and *XOR*) with conditional branch instructions. In example of Fig. 3(b), *OR* instruction (represented as *IORWF*) is replaced with *DECFSZ* instruction. *DECFSZ* instruction decrements a register value and skip next instruction only if its result is equal to 0. Such replacement of logical instructions with branch instructions are often observed both of boolean problems, this is because most of boolean calculation can be calculated by using conditional branches.

Since multi-step non-destructive evolutions does not also affect the calculation result in their evolution process, it is possible to decrease the program size by sequential genetic

operations. In particular, programs that size is smaller than 36 in Boolean1 and ones that size is 24 in Boolean2 are generated through this evolution.

**Multi-step destructive evolution** Although multi-step destructive evolution also generates small size programs by replacing several instructions with one or a few instructions such as multi-step non-destructive evolution, the selection probability of the program decreases in the process of evolution, *i.e.*, fitness decreases or program size increases. It is difficult to achieve this evolution because programs that are in the process of evolution can be removed from the population before generating small size programs. Examples are shown in Fig. 4, where colored instructions have same meaning in previous figures.

In an example of Arithmetic1, shown in Fig 4(a), a loop structure that calculates  $x^4$  with  $R4$  register is overwritten by a loop to calculate  $x^2$  with  $R2$  register. This loop overwriting enables a program to simultaneously calculate  $x^2 + x^4$  with  $R2$  register, and two instructions, *MOVF* and *ADDWF* which calculate  $R0 \leftarrow R2 + R4 (= x^2 + x^4)$ , at the end of the program becomes unnecessary which can be removed from the program. An example of Arithmetic2 removes three instructions colored in Fig 4(b), which gets same calculation result in different calculation process. Concretely, although a program calculates  $x^y$  with combination of bit shifting and adding before removing instructions, one after evolution calculates it with only adding. In an example of Boolean2, a program into which two instructions, *BTFSZ* and *IORWF*, is added has same calculation result as before adding them, and four instructions, *MOVF*, *ANDWF*, *MOVWF*, and *IORWF*, can be removed because they become unnecessary instructions due to added two instructions.

The common feature of these evolutions is that programs in the process of evolution has either incorrect calculation result or large program size. In Arithmetic1, since a program that only overwrites a loop structure includes two adding process, it does not correctly calculate result and has low fitness. In Arithmetic2, it is necessary to remove all of three instructions simultaneously, and if at least one instruction remains in the program, it cannot also calculate correct results. In Boolean2, if both of required two instructions are added, the program can correctly calculate result, however, its size increases. This feature results to decreases the selection probability of programs that are in the evolution process, and it becomes difficult to preserve such programs in a population. Therefore, it is indispensable to maintain the diversity of programs to achieve destructive evolution.

Multi-step destructive evolution is necessary to generate programs that size is smaller than 43, 17, 23 in Arithmetic1, Arithmetic2, and Boolean2, respectively. As results of Fig 2, although such evolution can be achieved in TAGP, SGPs can achieve in few trials. Particularly, SGPs never achieve

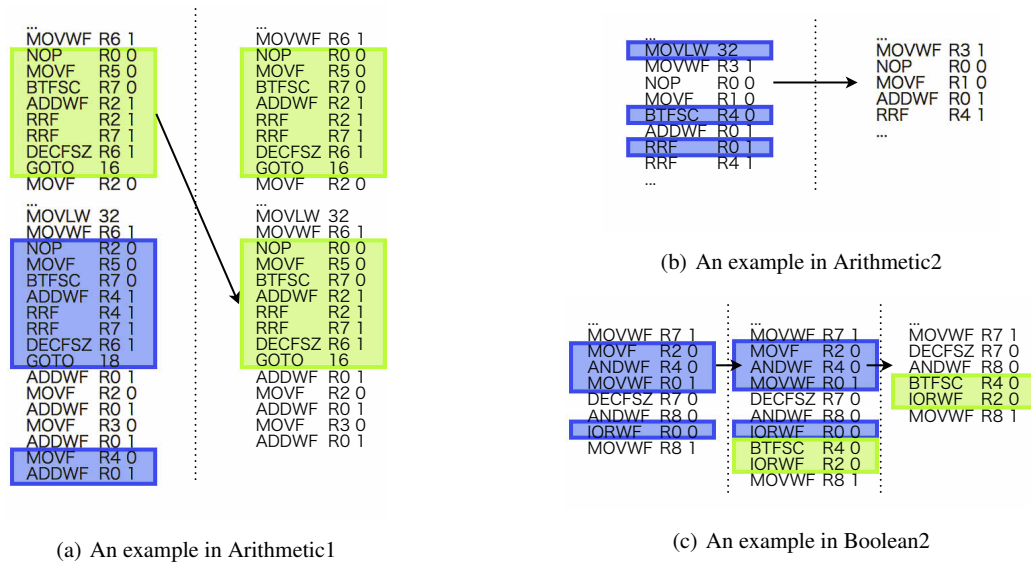

Figure 4: An example of multi-step destructive evolution

Table 7: Summary of program evolution analyses

	non-destructive	destructive
single-step	all GPs	-
multi-step	all GPs TAGP>SGPs	TAGP

this evolution in Boolean2, this is because Boolean2 requires more than three steps to generate programs that size is smaller than 23.

These results summarized in Table 7 reveal that SGPs achieve single-step non-destructive evolution which is easier than other evolutions. They, additionally, achieve multi-step non-destructive evolution in some trials. In contrast, it is revealed that TAGP cannot only achieve multi-step non-destructive evolution at a higher rate than SGPs (particularly in Boolean1), but also achieve destructive evolution which cannot be achieved SGPs. This result indicates that TAGP has higher evolution ability than SSGP and  $(\mu + \lambda)$ -GP.

### Discussion: diversity of programs

From the analyses of the program evolution, it is revealed that the diversity of programs is required to achieve complex program evolution. To confirm the diversity of programs in three GP methods, we verify the relation between the average fitness and the standard deviation of the program size in the memory/population of Arithmetic1 when a program that size is 44 and does not include unnecessary instructions is generated. Fig. 5 shows the scatter plot of the average fitness and the standard deviation of the program size for all

Figure 5: A scatter plot of the average fitness and the standard deviation of the program size in the memory/population of Arithmetic1

trials in Arithmetic1. In Fig. 5, the abscissa indicates the average fitness, while the ordinate indicates the standard deviation of the program size. The red points show the result of TAGP, the green points show the result of SSGP, while the blue points show the result of  $(\mu + \lambda)$ -GP. Note that the result of Arithmetic1 is only shown, but same trends are verified in other problems.

As shown in Fig. 5, it is indicated that both of SGPs have high average fitness and low standard deviation of the program size. This means that all programs in the population has very high fitness near the maximum, and also has similar program size. This result indicates that all programs are very similar to each other and the diversity of programs is very low. As mentioned in previous section, although the diversity of programs is required to generate a program that

size is less than 44 with either evolution cases, the diversities of SGPs are very low. From this result, it is revealed that it is difficult for SGPs to achieve multi-step destructive evolution because enough diversity of programs cannot be maintained.

While in TAGP, it is indicated that the average fitness is not maximum but is higher than 50, which is the half of the maximum fitness, and the standard deviation of the program size is also high. This indicates that TAGP can maintain lower fitness or larger size programs in the population, *i.e.*, several kind of programs are maintained. From this result, it is revealed that the high diversity of programs in TAGP contributes to achieve multi-step destructive evolution. This result advocates that TAGP have same feature of EAs using the asynchronous evaluation to maintain proper diversity of programs and to have high evolution ability.

### Conclusion

To investigate the evolution ability of TAGP as GP using the asynchronous evaluation, this paper compared TAGP with two simple GP methods, steady-state GP (SSGP) and GP using  $(\mu + \lambda)$ -selection  $((\mu + \lambda)$ -GP) as GP using the synchronous evaluation. Intensive comparisons among three GP methods were conducted in four computational problems to minimize the size of an actual assembly language program.

We classify the evolution processes to two categories, *non-destructive evolution* and *destructive evolution* depending on whether the evolution process affects calculation results or not. The experimental result has revealed that the following implications: (1) TAGP has higher evolution ability than SSGP and  $(\mu + \lambda)$ -GP, *i.e.*, TAGP cannot only achieve *non-destructive evolution* which is easy to be accomplished, but also achieve *destructive evolution* which cannot be achieved by SSGP and  $(\mu + \lambda)$ -GP; and (2) the diversity of the programs in TAGP can derive a high evolution ability in comparison with SSGP and  $(\mu + \lambda)$ -GP. In detail, such diversity is indispensable to *destructive evolution*.

The following issues should be pursued in the near future: (1) experiments on other problems such as classification, (2) a comparison with other GP methods, (3) an improvement of evolution ability of TAGP, and (4) a parallelization of TAGP.

## Abstract

In this paper, a gene regulatory network called FGRN (Fractal Gene Regulatory Network) and a reaction-diffusion system called AHHS (Artificial Homeostatic Hormone System) are investigated for spatial pattern formation. The two bio-inspired controllers possess similar and different features in terms of their underlying processes, structures, and communication abilities. By comparing their behaviours and capabilities in pattern formation, we provide a deeper understanding of the effects of their features. The controllers are evolved and investigated for producing various patterns in presence of different implicit positional information as well as developing a memory in order to keep the desired pattern when the positional information is eliminated. The behaviours of the controllers in each case are discussed and a preliminary test of robustness is performed. The experiments represent a positive impact of diffusion process in AHHS that is compensated by the complex structure of FGRN in producing patterns in presence of positional information and a negative effect of diffusion process in memory capability.

## Introduction

Formation of spatial patterns is a challenging subject both in biological and artificial organisms. Different forms with various levels of complexity are found everywhere in nature. One of the challenges in developmental biology is to understand the underlying processes that control the pattern formation (Jaeger and Martinez-Arias (2009)). On the other hand, from the point of view of multi-modular robotics, a proper behaviour emerges from a proper pattern of roles assigned to the modules across the body of a robot.

A problem encountering pattern formation is symmetry-breaking. In biological organisms it happens at early developmental phases. As it was suggested by Wolpert (1968) and is found in embryos, e.g. fruit fly *Drosophila melanogaster* (Driever and Nusslein-Volhard (1988); Ephrussi and Johnston (2004)), the polarization of an organism is induced by some maternal cue in the form of morphogen gradients. By using these gradients in the environment of the organism, some information is provided that is used for localization of the organism's units (cells) and participates in the process of development. The same concept is useable in artificial organisms (e.g. localization of modules in a modular robot).

For subdivision of a body using positional information, Wolpert (1968) proposed a French-flag model. The model is composed of three stripes with different colours along the body and is used by many researchers with different approaches of evolving systems (e.g., Miller (2003); Bowers (2005); Cussat-Blanc et al. (2011)).

In the field of artificial life and evolutionary computation, various models are inspired by genetic and chemical systems in biological organisms. Gene Regulatory Networks (GRNs) and reaction-diffusion models are two examples of these systems that have drawn attention in the recent years. They consist of a number of different underlying processes that control their dynamics. Although the source of inspiration and the details are different for these two models, but there are some similarities between the models. In this work, a reaction-diffusion model and a GRN model are investigated in the context of pattern formation.

GRNs are inspired by internal interactions between genes and proteins in cells. Various models of computational GRNs have been defined and investigated from different perspectives, e.g. studying dynamics (Banzhaf (2003)), applying for morphology development (Eggenberger (1997); Roggen and Federici (2004)), developing both morphology and controller of robots (Bongard and Pfeifer (2001)).

Fractal Gene Regulatory Network (FGRN) (Bentley (2004b)) is an example of GRN models. It is originally designed as a single-unit of control and successfully implemented for different tasks, i.e., controlling conventional robots (Bentley (2004a)) and pole-balancing (Krohn and Gorse (2010)). Since no explicit communication mechanism between different units is defined in FGRN, environmental feedback is used to coordinate modules in multi-modular robotic applications of FGRN (Zahadat et al. (2010, 2012)).

Reaction-diffusion models are inspired by intracellular signaling in biological organisms. The models contain both a process of local reaction between substances and diffusion of substances across the organism. Artificial Homeostatic Hormone System (AHHS) is an example of these models which is originally introduced in Schmickl and Crailsheim (2009) and has been used successfully in robotic applica-

tions for both single and multi-modular robots (Stradner et al. (2009); Schmickl et al. (2010); Hamann et al. (2010)).

In this paper, FGRN and AHHS are evolved and investigated for generating target patterns with fixed maternal morphogen gradients as well as generating a memory such that the target pattern is preserved after elimination of the maternal gradients. Behaviours of different evolved solutions are discussed and a sample evolved controller is tested for its reaction against an instant reset in a single unit in order to have an evaluation of robustness of the produced pattern.

While the two systems are similar in terms of having mechanisms to produce various mappings between input and output as well as forming internal feedback loops, they are different in their complexity and details of mechanisms, structure, and communication abilities. For instance, FGRN model provides more complicated interaction network between local substances in comparison with AHHS. A prominent difference between the two models is the lack of intra-unit communication in FGRN. Due to that, the spatial patterns generated by FGRN lay solely on the maternal gradients and internal interactions of each particular unit. On the other hand, in AHHS, along with the maternal gradients and internal interactions, the pattern formation can benefit from the diffusion of substances over the units.

In this work, in addition to FGRN and AHHS with their standard underlying processes, a diffusion-free version of AHHS has been also implemented in order to investigate the importance of diffusion in the observed differences between the behaviours of FGRN and AHHS.

### Short Summary of FGRN

FGRN (Bentley (2004b)) is a GRN model that uses an abstract model of proteins, called fractal proteins, as the means of interaction between genes. These means of interactions are encoded in the genome and evolved by a version of Genetic Algorithm (GA) (see Bentley (2004b) for details).

The genome consists of a number of genes and parameters. Every gene in the system belongs to a type of genes: input genes, output genes, regulatory genes and receptor genes. Input, regulatory and receptor genes encode corresponding fractal proteins. A fractal protein has a shape and a concentration level. The shape is encoded in a gene by three real values. These values determine a square window on Mandelbrot fractal set. A protein's concentration level is a variable value. The changes in concentration level is controlled by the other proteins' concentration levels, shapes of the fractal proteins, and other parameters of the genome. To every sensory input into an FGRN system, a set of input proteins are associated. The input value determines the concentration levels of the corresponding input proteins and consequently participate in driving the dynamics of the system. Receptor proteins act as filters over inputs by manipulating shapes of input proteins. Regulatory proteins participate in driving the internal dynamics. Their concentration levels are

both controlled by and also participate in controlling the dynamics of the system. In fact, they make regulatory connections in the network of proteins and are potentially capable of establishing recurrent loops and act as a sort of memory in the system. Output genes determine the influence of the concentration levels of the proteins on the output of the system. (For a detailed introduction of FGRN see Bentley (2004b))

FGRN can be seen as several systems of Difference Equations ( $O\Delta E$ s) where each  $O\Delta E$  system controls the internal dynamics over time in a particular part of the state space. Concentration levels of proteins are state variables of the system. When the value of a state variable changes from a positive value to zero or vice versa, the system switches between different parts of the state space and its behaviour changes due to activation of a different system of  $O\Delta E$ s (For a detailed description of this representation of FGRN see Zahadat and Støy (2012)). Table 1 demonstrates an example FGRN represented as conditional sets of  $O\Delta E$ s.

Table 1: An example of a simple FGRN as several conditional sets of  $O\Delta E$ s. The state-space of this system is divided into four parts.  $S$  represents the set of proteins with positive concentration levels indicating a division of the state-space.  $P_1$  and  $P_2$  correspond to an input and a regulatory protein respectively and  $p_1$  and  $p_2$  are their corresponding concentration levels.  $out$  is the output of the system.

condition	equation set
if $S = \{P_1, P_2\}$	$p_2 \leftarrow 0.8p_2 - (0.2p_1 + 0.5p_2)$ $\quad \times \tanh(0.6p_1 + 1.5p_2 - 3.6) - 0.2$ $out \leftarrow 0.15p_1 + 0.2p_2 + 4$
if $S = \{P_1\}$	$p_2 \leftarrow 0.4p_1 + 0.5$ $out \leftarrow 0.32p_1 + 2$
if $S = \{P_2\}$	$p_2 \leftarrow 0.8p_2 - 0.25p_2$ $\quad \times \tanh(0.5p_2 - 0.4) - 0.2$ $out \leftarrow 0$
if $S = \{\}$	$p_2 \leftarrow 0.4$ $out \leftarrow 0.25$

Due to the lack of any intra-unit communication in FGRN, symmetry breaking and differentiation of units is achievable by providing different inputs for different units.

### Short Summary of AHHS

AHHS (Artificial Homeostatic Hormone System) (Schmickl and Crailsheim (2009)) is a reaction-diffusion-based system inspired by Turing process (Turing (1952)) that describes processes of natural pattern formation and growth.

An AHHS is defined by a set of artificial hormones and a set of rules. The rules define how sensory input and hormone concentrations participate in changing the concentrations and outputs of the system. Both hormones and rules are evolved by using a standard real-valued GA.

An AHHS can be represented as a dynamical system consisting of several state variables (hormone concentrations) and a system of  $O\Delta E$  that governs their dynamics. The key feature of AHHS is how the parameters of this  $O\Delta E$  are encoded and determined. Concentrations of the hormones are

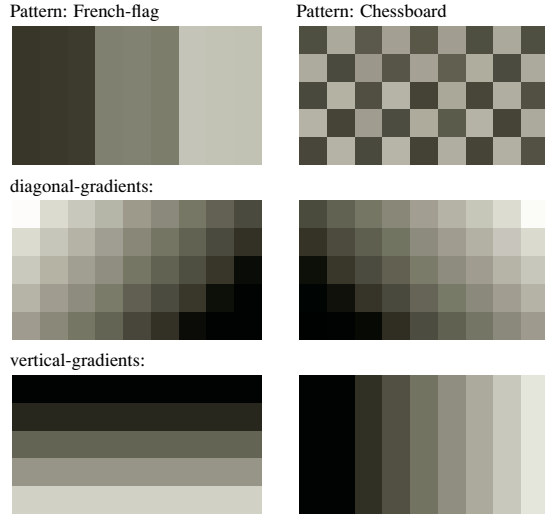

Figure 1: Target patterns (first row), diagonal gradients (second row), and vertical gradients (third row).

allowed to increase independently by a base production rate and are also subject to a certain decay.

The dynamics of hormone concentration  $H$  at time  $t$  is defined for hormone  $h$  as follows:

$$\frac{\Delta H_h}{\Delta t} = \alpha_h + D_h \nabla^2 H_h(t) - \mu_h H_h(t) + \sum_i \mathcal{L}_i(t), \quad (1)$$

where  $\alpha_h$ ,  $D_h$ , and  $\mu_h$  are base production rate, diffusion rate, and decay rate of hormone  $h$  respectively.  $\mathcal{L}_i(t)$  is the influence of rule  $i$  on hormone  $h$  and is defined as:

$$\mathcal{L}_i(t) = \theta(H_k(t))(H_k(t)\lambda_i + \kappa_i), \quad (2)$$

$$\theta(x) = \begin{cases} 1 & \text{if } \min_i < x < \max_i \\ 0 & \text{else} \end{cases}, \quad (3)$$

where  $\lambda_i$ ,  $\kappa_i$ ,  $\min_i$  and  $\max_i$  are parameters of the rule.  $\theta(H_k(t))$  determines if the rule is triggered or not. If the rule is triggered, the concentration of hormone  $h$  changes linearly based on concentration of hormone  $k$ .

In the current implementation, sensory inputs are scaled in the range of hormone concentrations  $[0,1]$  and directly set to the concentration level of particular hormones. In the same way, concentration level of a particular hormone is considered output of the AHHS unit.

## Experiments

In this work, the systems are evolved to produce patterns in a  $5 \times 9$  rectangular grid. Every cell of the grid has a colour which is determined by the output of its controller. The controllers are genetically identical all over the grid. Two maternal gradients are provided over the grid in every experiment.

Two types of target patterns and two types of maternal gradients are considered with different degrees of difficulty (see Figure 1 for both target patterns and maternal gradients). For the FGRN controllers, the two maternal gradients enter a unit in form of two sensory inputs that in turn influence the concentration levels of input proteins of the unit. In AHHS system, the values of the maternal gradients directly set the concentration levels of two particular hormones. The output from each unit (either a FGRN or AHHS controller) is mapped into one of the three predefined colours regardless of the number of colours in a particular target pattern.

The controllers are evolved for the following tasks:

- Since French-flag pattern as suggested in Wolpert (1968) is a benchmark in evolving for pattern formation, in the first task, the target pattern is a French-flag with vertical maternal gradients (third row of Figure 1). In this case we suspect that the controllers make a direct mapping between one of the maternal gradients and the output.
- In the second task, the target pattern is again a French-flag but this time the maternal gradients are diagonal, as in Cussat-Blanc et al. (2011) (second row of Figure 1).
- The third task aims at producing a chessboard pattern with diagonal maternal gradients. In the first three tasks, the system runs for 100 time-steps while the gradients are stable during the run-time.
- In the forth task, the controllers are supposed to produce a sort of memory. The gradients are presented for the first few time-steps when the target pattern is generated. Then the gradients are removed while the target pattern is expected to be preserved by the system. The simplest combination of target pattern and gradients (French-flag with vertical gradients) is chosen for this task in order to keep the focus on the memory capability.

## Evolving for the target patterns

Populations of 50 random individuals are evolved for each task for FGRN, standard AHHS, and diffusion-free AHHS controllers. Every experiment is repeated for 10 independent runs with 1500 generations. Table 2 represents the controller and evolutionary settings.

Table 2: Controller and evolutionary settings

FGRN:

population-size	50	#generations	1500	#recomb.	0.4
mut. prob.	1	#receptors	2	#inputs	2
#regulatory	2	#outputs	2		

AHHS:

population-size	50	#generations	1500	recomb. prob.	0.01
mut. prob.	0.4	#hormone	6	#rules	30

In the first three tasks, fitness is defined as the number of correct coloured cells in the final pattern. In the case of evolving for memory, two fitness factors are required. A fitness factor is required to direct the evolution towards generating target pattern and the second factor is needed for evolution of the memorizing ability. Considering these factors, fitness is defined as a combination of the number of correct colours in the last time step with maternal gradient (time-step 10) and the average number of correct colours in all the next time steps:

$$fitness = 3 \times C_{T_p} + \frac{1}{T - T_p} \sum_{t=T_p+1}^T C_t$$

where  $T$  is the number of time-steps of the experiment and in the first  $T_p$  time-steps the gradient is present,  $C_{T_p}$  is the number of correct colours in time-step  $T_p$ , and  $C_t$  is the number of correct colours in time-step  $t$ .

Comparisons between FGRN, standard AHHS, and diffusion-free AHHS controllers for all the tasks are represented in Figure 2. The figure represents that FGRN and AHHS are evolvable to produce the pattern for all the tasks while none of the runs of diffusion-free AHHS produces a perfect French-flag and chessboard with diagonal gradient. Figure 3 demonstrates the median fitness-progression of the controllers over generations. The figure represents that the French-flag is easy-to-produce for all the controllers when the gradients are vertical. In the case of diagonal gradients for both French-flag and chessboard, diffusion-free AHHS has the lowest fitness indicating that diffusion has a positive effect for AHHS in these tasks. In the case of evolution for memory, diffusion-free AHHS makes higher fitness than standard AHHS while FGRN represents the highest value. It implies a negative effect for diffusion in keeping a pattern without external clue of maternal gradients.

### Looking at the behaviours

In order to make an impression of the solutions of each controller type, we will have a look at the behaviours of the evolved controllers in the following sections. Representative examples of different observed behaviours in each task are displayed in Figure 4. Each curve in the figure represents the development of fitness achieved by an example controller over time (Note that the fitness in the last time-step is considered the actual fitness of the controller).

**French-flag with stable vertical gradients** All the three types of controllers are able to produce perfect target pattern. The difference between the number of successful runs is not statistically significant (Figure 2).

In FGRN, 9 runs out of 10 produce target pattern perfectly. In six runs out of 10, the pattern is perfectly generated from the first time-step that represents that static controllers are found that simply threshold the maternal gradients to produce the output that is mapped to the respective

colours. The other three runs reach the perfect pattern after less than 20 time-steps and then the pattern stays stable.

In AHHS, 9 out of 10 runs produce perfect pattern. In four runs, the output oscillates between different patterns such that in time-step of observation (time-step 100) the perfect pattern is represented. In the other five runs, fitness increases gradually and perfect pattern is produced after several steps and stays stable until time-step 100. Generation of perfect pattern is slower than similar cases in FGRN.

In diffusion-free AHHS, 9 runs out of 10 generate the pattern. Five runs generate oscillatory patterns such that the target pattern is represented in time-step 100. In the other four runs, the pattern is slowly produced during time and stays stable. The increase in fitness is again slower than FGRN but no significant difference with standard AHHS is observed.

**French-flag with stable diagonal gradients** In FGRN, four runs out of 10 reach the perfect pattern. Three of them make the correct pattern from the first step indicating thresholding of the maternal gradients. The other run, makes the pattern after about 10 steps. The unsuccessful runs mainly produce changing patterns with chaotic oscillation in the fitness curve, although a static pattern is observed in one run.

In AHHS, four runs produce the perfect target pattern. All the four successful runs generate the correct pattern very slowly and gradually in last time-steps. In all the other runs the fitness gradually increases during time although short decreases are also not impossible. No oscillation is observed.

In diffusion-free AHHS, none of the runs are successful to produce perfect target pattern. Changing patterns with both chaotic and ordered oscillations and also patterns with gradual increase in the fitness are observed.

**Chessboard with stable diagonal gradients** In FGRN, three runs reach the perfect target pattern and two other runs are correct except for one cell of the grid. Although we suspected that the success of FGRN in this case might be a result of precise thresholding but the patterns oscillate over time such that the perfect pattern is presented in the last time-step. In fact all the ten runs make oscillatory patterns mostly with big differences from one step to the next.

In AHHS, one run reaches the perfect pattern. This pattern is not stable and oscillates between the correct and the inverse patterns such that in the last time-step the perfect pattern is presented. The oscillation is more ordered comparing the FGRN runs. Most of the other runs produce oscillating patterns but stable patterns are also observed.

In diffusion-free AHHS, no run produces the perfect pattern. The runs generate different patterns and although some stable patterns are generated but most of the runs make oscillatory patterns. In comparison with AHHS, ordered oscillations with high frequencies are not common and oscillations are more chaotic and in comparison with FGRN the oscillations have lower frequencies.

Figure 2: Fitnesses of the best individuals in the last evolutionary generation for FGRN, AHHS, and diffusion-free AHHS controllers for the four tasks. Box-plots indicate median and quartiles, whiskers indicate minimum and maximum, circles indicate outliers (values are collected from 10 independent runs).

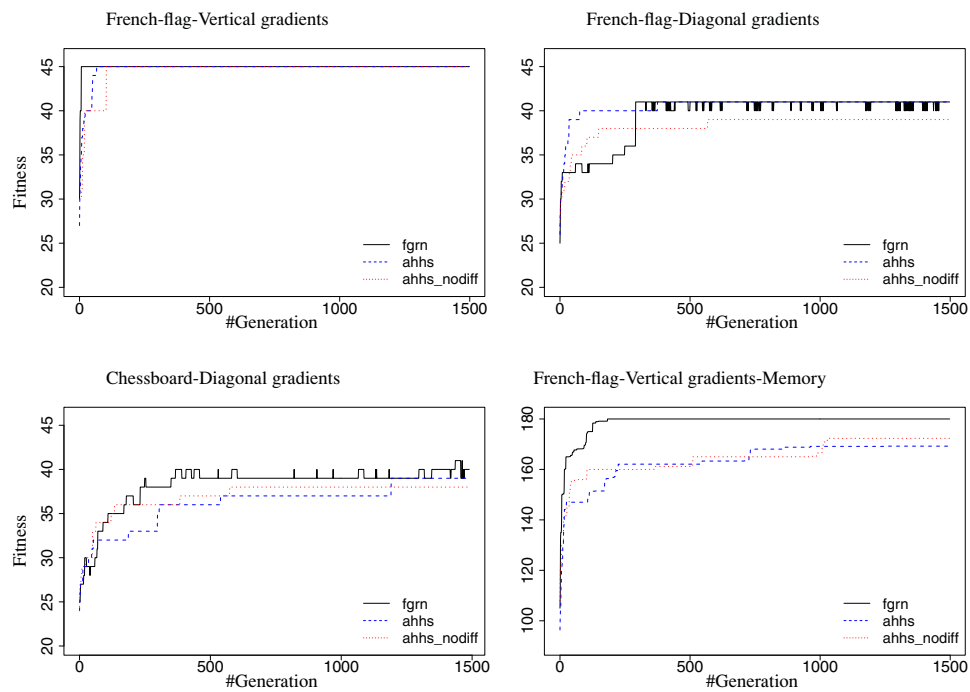

Figure 3: Comparison of fitness trajectories for FGRN, AHHS, and diffusion-free AHHS controllers in the four tasks. The values are medians of the best fitnesses in the 10 independent evolutionary runs. (y-axis starts from 20 due to the space-limitation and since there is no data below 20.)

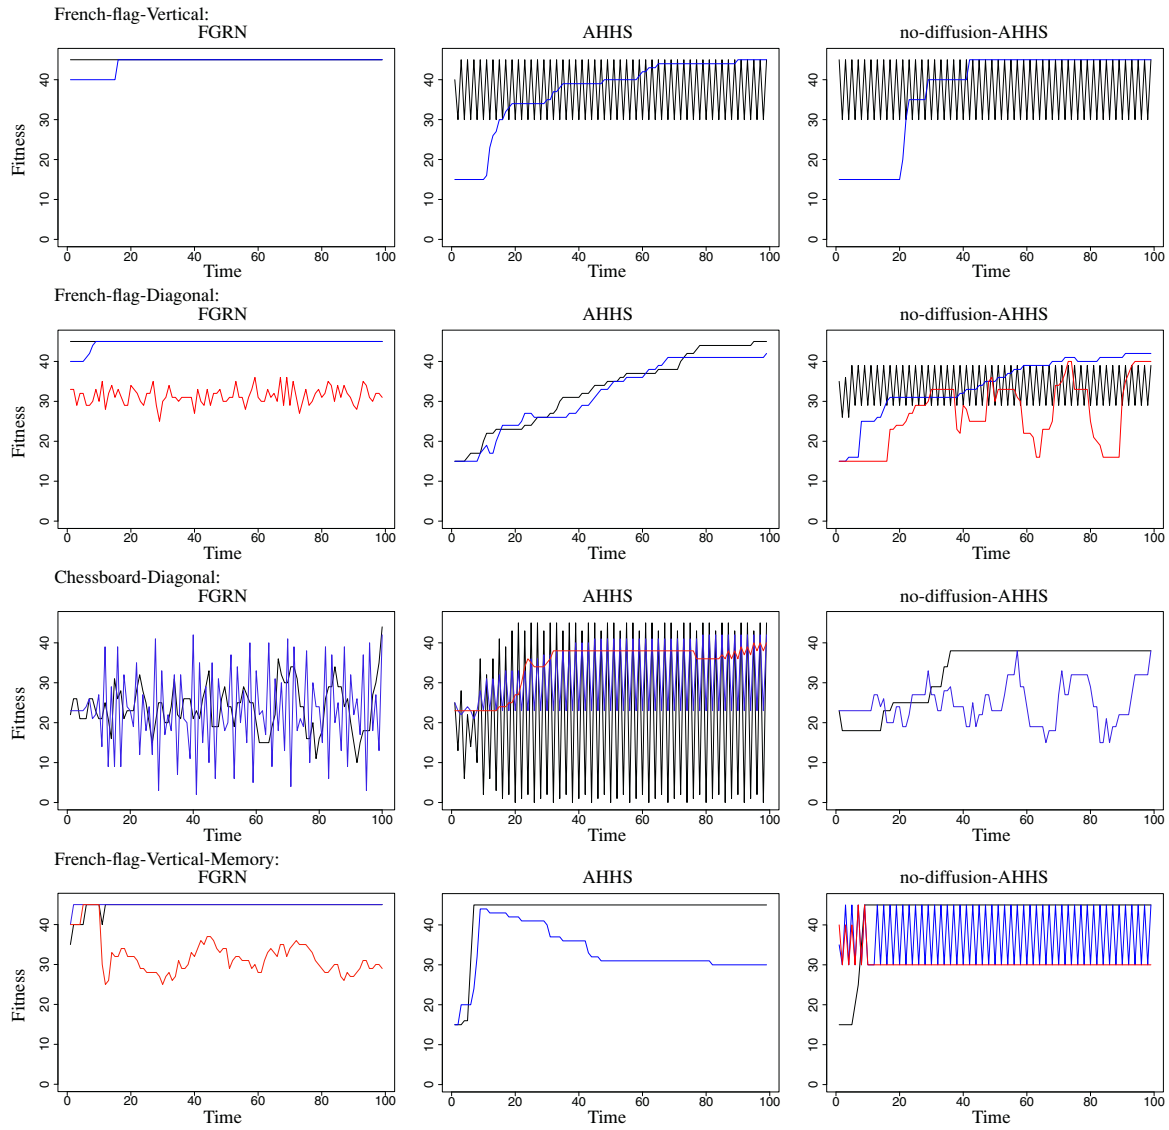

Figure 4: Fitness development over time for representative examples of the evolved solutions for the three controller types.

Figure 5: Behaviour of example controllers when all the state variables of the cell in the middle of the grid is reset to zero in a particular time-step that is represented by the vertical dashed-lines. The diagrams are squeezed due to space-limitation.

**Memory in French-flag with vertical gradients** In FGRN, four runs are successful in producing the pattern at time-step 10 (last time-step with gradients) and keeping it for the next 90 time-steps (with no gradient). In three other runs, only for one step after vanishing the gradient, the pattern is disturbed and then is regenerated. In the other three runs, the target pattern is produced in time-step 10 but then it changes and the fitness oscillates chaotically or ordered.

In AHHS, in two runs the pattern is produced until time-step 10 and is kept until the end. In one run, the pattern is represented in time-step 10, but when the gradients are vanished the pattern slightly deviates from target for few time steps but again is generated and kept until the end. In another run, the perfect pattern in time-step 10 is kept for about 60 time-steps and then deviates from target in a single cell of the grid until the end. In all the rest except one, the target pattern is represented in time-step 10, but then it deviates from target when the gradients are vanished.

In diffusion-free AHHS, five runs produce and keep the perfect target pattern from time step 10 to 100. In one run, the produced pattern in time-step 10 is perfect, then it changes in the next time step when the gradients are vanished but it is produced again after one step and is kept until the end. This is the effect that is also observed in FGRN. In one run, the pattern is switched between the target and a simpler pattern in every step. The other three runs produce the target pattern in time-step 10 and then the pattern changes to a simpler pattern and stays stable until the end.

### Robustness in example controllers

In the last experiment we aim to evaluate robustness of the controllers by disturbing the internal variables of a cell in the grid in order to see if the correct pattern is regenerated after few time-steps. Experiments are performed with the French-flag pattern in the three cases of stable vertical gradients, stable diagonal gradients, and memory with vertical gradients, for all the controller types. In each case, we chose a controller from the previous experiments that produces the target pattern long before the end of evaluation period. Then the controller is used to produce the pattern and in a particular time-step all the dynamic values (hormones/proteins) of the controller in the middle of the grid are set to zero. The fitness of the system at the end of the evaluation period is then calculated that represents whether the pattern is regenerated or not. The results are represented in Figure 5. Since diffusion-free AHHS did not evolve for French-flag pattern with diagonal gradients in any of the runs, it is omitted in the figure. The figure demonstrates no change in any of the patterns produced by FGRN controllers indicating robustness of the controller against the reset. In AHHS controller, for the stable vertical gradients the pattern does not change after reset. In the stable diagonal gradients, the pattern changes (fitness decreases) but it is reproduced after few time-steps. In the case of memory as well as the tasks with diffusion-free

AHHS, the patterns do not regenerate after reset.

## Conclusions

FGRN (Fractal Gene Regulatory Network), standard AHHS (Artificial Homeostatic Hormone System), and a diffusion-free AHHS are evolved and investigated for their capability in pattern formation in presence of maternal gradients.

FGRN is computationally expensive due to encoding of proteins as the intermediate substances that establish interaction connections between genes. By this indirect encoding, a potentially complex interaction network of genes is formed. FGRN defines no communication mechanism between units and all the dynamics of the system are based on the internal interaction network. On the other hand, AHHS is a reaction-diffusion-based model and employs diffusion as a means of communication between units. In AHHS, the interaction connections between hormones are directly encoded which provides a simpler interaction network inside a unit, in comparison with FGRN. The dynamics of the system is based on both the internal interaction network and the diffusion mechanism.

In this work, three sets of evolutionary experiments with different combinations of target patterns and stable gradients are performed. In addition, a memory test experiment is performed where the maternal gradients are provided in the first time-steps and then they are vanished from the environment. The system is expected to produce the target pattern in presence of maternal gradients and keep it intact after elimination of the gradients.

In all the three experiments with stable maternal gradients, both FGRN and standard AHHS are successfully evolved for the perfect solution although the rates of success are different. It has to be mentioned that in a previous work by Cussat-Blanc et al. (2011), successful evolution of another GRN model (Banzhaf (2003)) in the case of French-flag with diagonal gradients was reported where the result of a single evolutionary run was presented. Diffusion-free AHHS is evolved successfully for producing the French-flag pattern in presence of vertical maternal gradients but it did not find the solutions in more complicated tasks of producing chessboard pattern and French-flag with diagonal maternal gradients. It implies that diffusion is an important part of an AHHS system. On the other hand, despite of importance of diffusion in AHHS, FGRN is also successful in all the tasks. It indicates that in principle the investigated patterns are producible even without diffusion. The more complicated nature of FGRN system enables it to be evolved for the proper patterns although there is no communication mechanism implemented in FGRN. In addition, observing the evolved solutions for French-flags (both gradient types) represents that FGRN can produce the pattern in one time-step while AHHS always needs time to build it up. This is also due to the complex structure of FGRN in terms of  $O\Delta Es$ .

All the three types of controllers were successfully evolved for the memory experiment. The rate of success (number of perfect evolutionary runs) was lower for standard AHHS in comparison with diffusion-free AHHS and FGRN. It can lead to the conclusion that diffusion has a negative effect in keeping the memory. This effect is intuitively expected, since diffusion tends to flatten the pattern and having that in the system requires a compensation mechanism, e.g. elaborating internal feedback loops.

A preliminary experiment for evaluating robustness of the systems has been also performed in this work and represented the highest robustness for the solutions generated by FGRN system. In the future, controllers with different subsets of internal processes will be evolved for series of spatial patterns with increasing levels of complexity and the effects of the internal processes will be investigated in details.

# Multiplicity of Interpretation in an Asynchronous Updating Rule: Emergence of Collective Cognition

Takayuki Niizato<sup>1</sup>

<sup>1</sup>Faculty of Engineering, Information and Systems, Tsukuba University, Japan  
t.niizato@yahoo.co.jp

## Abstract

Many kinds of interactions among individuals construct collective animal behavior, but how to apply this multiplicity of interactions is often unclear when constructing models. We propose multiplicity of interaction in a simple model constructed from three factors: asynchronous updating, learning site patterns, and agent anticipation. We found that the first two contribute to an efficient searching strategy, and that adding agent anticipation enables sign making (avoidance) in heterogeneous environments. Our model surprisingly suggests that searching strategies and territorial behavior such as boundary marking — seemingly contradicting behaviors — emerge from two aspects of our simple interaction rule. We discuss the possibility of collective cognition in animals when heterogeneous environments change. Our study suggests that multiplicity of interaction in asynchronous updating is very important for understanding many aspects of emergent collective behavior in animals.

## Introduction

Collective animal behavior results from many kinds of interactions among individuals, and interactions vary flexibly according to the situation encountered by individuals (Couzin, 2009; Sumpter, 2006). In self-organization models, behaviors can emerge by tuning some parameters (Couzin, 2009; Haken, 1983; Sumpter, 2006). However, in most cases these various behaviors are monotonic. For example, flocking behavior can form swarms, tori, or polarized groupings by tuning interaction ranges. This is monotonic behavior because it is a variation of a single aspect, in this case alignment (Couzin, 2009). Self-organization has been discussed from many aspects, but it is increasingly important to consider theoretical aspects of the essential diversity of behavior, which sometime seems mutually irrelevant or even contradictory. The emergence of various behaviors in self-organization traces back to the concept of the “subsumption architecture” proposed by Brooks /citepBrooks. Subsumption architecture can be summarized in two aspects, namely, that agents (or robots) never need representations and that the behavior of subjects in a lower layer such as object avoidance finally emerges in higher-layer behavior such as environment searching (Brooks, 1990). Most importantly,

multiple simple behaviors ultimately form qualitatively different collective behavior. To account for the above, we propose a new model of self-organization in collective animal behavior using an asynchronous updating method. In our model, each agent uses scent marking at each site passed. Scent markings are often observed in real systems, such as ants, wolves, and other animals (Cornforth et al., 2005; Giuggioli et al., 2011; Lewis and Murray, 1993).

Although there is a wide range of scent marking behavior in actual phenomena, we can consider their common properties, namely that scent marking gives collective information about where the animal lives (Giuggioli et al., 2011; Lewis and Murray, 1993). Animals thus demonstrate collective decision-making using this information. However, information about locations in scent marking inevitably has a multiplicity of meanings, because the agent’s interpretation of the information would rely heavily on the situation. In our model, asynchronous agent actions give many interpretations, or multiplicities, to this scent marking. When each agent interacts with neighbor sites of locations and other agents, our model divides asynchronous updating of agent states into an active phase and a passive phase. In the passive phase, agents only memorize their environment and obey stochastic rules. In the active phase, agents use the memorized state against their environment. As we will show, these two interaction phases, induced by asynchronous updating, exhibit non-trivial collective searching behavior compared with the normal model. The remainder of this paper is organized as follows: In section II, we describe the algorithm of our asynchronous learning model (ALM) and present the effect of two phases of interaction for collective searching behavior. In section III, we introduce “anticipation” for each agent in ALM to develop an asynchronous learning model with anticipation (ALMA). This anticipation incorporates past and future information with current information when an agent decides its next action. We show the anticipation of each agent contribute to sign making, an avoidance, for heterogeneous environments. Finally, we discuss the possibility of collective cognition for changing environments.

## Result

### Asynchronous Learning Model (ALM)

Our ALM is mainly divided into two parts, site pattern learning induced by asynchronous updates and asynchronous updating with anticipation. These two parts can be considered as one, but division clarifies the effect of these two factors. We define the neighborhood of each agent as a Moore neighborhood, meaning there are eight sites around an agent of interest. There are three site patterns: occupied, scent marked, and vacant. There are therefore  $3^8 - 1 = 6560$  neighborhood patterns.

In this section, we examine the effect of pattern learning using asynchronous updating. First, we divide the method of agent interaction into an active phase and a passive phase. Using asynchronous updating means there are two neighbor site patterns where each agent interacts with its environment (Figure 1). One is the case of no other agent around the agent whose turn it is. This case would be common in early turns, or in a low-density environment. The other case is that there are agents at the neighbor sites of the agent whose turn it is. This case is common in late turns, or in high-density environments. These are called active and passive phases, respectively. These two interaction phases have an important place in our agent interaction model.

We next assign different roles to these two phases. In the passive phase, some agents have already occupied the agent's neighbors on its turn. Assuming the agent cannot move to these occupied sites, it must select from the remaining unoccupied sites, which correspond to vacant sites or scent marked sites. Unoccupied sites are selected stochastically. Our model assigns a high selection probability to scent marked sites and a low selection probability to vacant sites. The ratio between these two probabilities,  $\text{Prob}(\text{Vacant})/\text{Prob}(\text{Scent})$ , is represented by a parameter  $\mu$  ( $0 < \mu \leq 1$ ). We will see that a low value for  $\mu$  results in agents aggregating through the use of their scent marking. Furthermore, each agent learns (or memorizes) the pattern of neighbor sites (Figure 1, Right).

Next, We set properties in the active phase. Agents used stored information corresponding to the current pattern of neighbor sites to the pattern memorized in the passive phase. The current site pattern is therefore replaced with another site pattern, which almost always includes some occupied (or block) sites. Each agent uses this stored information and stochastically selects one site from among the sites that can be moved to. Using stored information thus affects agent interpretation of the environment.

We divide the roles for the active and passive phases, respectively, as using stored information and learning the site pattern. Because asynchronous movement can create timing conflicts, there is always room for multiple interpretations of a given site pattern in one time interval. Note that the asynchronous update is not a random order scheme, but a density order scheme; high-density agent neighborhoods

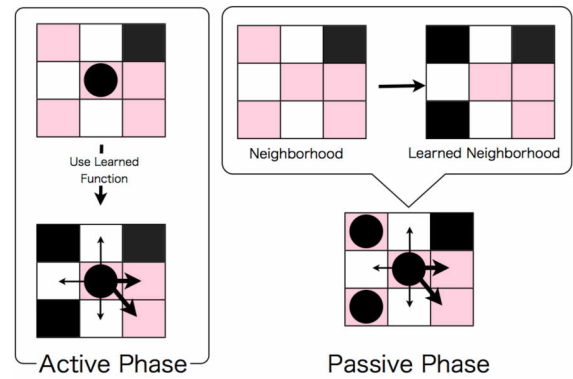

Figure 1: A sketch of the algorithm. Black circles correspond to agents. Each site color shows its state. White corresponds to a void site, pink corresponds to a scent marking site, and black corresponds to an occupied site. Each agent interacts with its neighborhood in an active phase or passive phase. The size of arrows represents the degree of the weight.

tend to be selected first, and agents with low density move last. We count as one step all agents being updated using density-dependent asynchronicity.

### Searching Strategy in ALM

Now we examine the effect of multiple site pattern interpretations induced by the asynchronous updating method. To clarify this effect, we introduce a control model constructed using asynchronous updating without site pattern learning in the active phase. In other words, there is no conflict regarding interpretation of the site pattern between the active phase and the passive phase. The parameter  $\mu = 0.001$  is the same as in the control model and the number of agents is 150.

Figure 2 shows a distribution of agents on a  $35 \times 35$  grid for our model and its control. Each color corresponds to the state of the sites. Red corresponds to an agent, pink corresponds to a scent marker, black corresponds to a block (such as an occupied site) and white corresponds to a vacant site. As compared with ALM, agents in the control model clearly form a small aggregation, meaning they are connected by their scent markers. Once agents in the control model form a local group, they hardly move.

In contrast, asynchronously updated agents with learning never broadly cover the space, they instead form aggregations, suggesting that agents with learning connect with each other to effectively search over the entire space, unlike the control model (ALM without learning). Scent markers were originally attractive signs, as we observe in the control model. The asynchronous update with site pattern learning shows an additional ability, collective searching behavior. In fact, Figure 3 shows that mean cover rate of scent marking

Figure 2: Agent distribution on a  $35 \times 35$  grid. The left figure shows the control model, and the right figure shows ALM. Agent colors correspond to interactions; red agents are in the active phase, and blue agents are in the passive phase. The black tail with each agent represents a trajectory in a few steps.

Figure 3: Mean cover rate of scent marking. The ALM value (light gray) is higher than the control model value (gray).

area is larger than the control. This result suggest agent in ALM do more efficient searching than the control model despite the almost same mechanism.

This additional ability is because of the repulsion effect against dense spaces when an agent uses site pattern learning in the active phase. No agent keeps staying in the same group, due to this repulsion effect. In other words, the conflict (or difference) between the active phase and the passive phase allows multiple interpretations of the environment for each agent.

From an ecological perspective, this difference is important. Generally speaking, animals live in groups, which has advantages in reproduction and vigilance against predators (Jackson, 2006; Johnson et al., 2002; Parrish, 1999). Forming groups is therefore an essential problem for living animals. Group living can also be an issue for individuals, however, because resources are finite and large groups increase the risk of detection by predators. So there is a trade-off between the advantages and risks inherent to group living. Group size optimization is therefore essential for group

living (Johnson et al., 2002). Our model suggests that multiple interpretations induced by the asynchronous updating method are a natural connection between group formation and decreasing the risk of large groups. In other words, agents in ALM can decrease their risk of food exhausting because each group never stays the same place. Furthermore, we point out the role of weak connection among small groups. Small groups in weak connections can decrease the risk of detection and group's isolation.

### ALMA (ALM with Anticipation)

Now we examine the effect of agent anticipation, defined as incorporating current information with past and future information. The detail of algorithm is listed on **Appendix C**. Current information corresponds to the site pattern of the agent's neighborhood, as discussed concerning the active phase with learning in ALM. To extend this approach, we consider the neighborhood of the neighborhood, in other words all eight neighborhoods of sites reachable in one step. This corresponds to past and future information, because these sites include the site belonged to one step ago, or that which will be belonged to one step from now (see upper left of Figure 4). We can organize these nine site patterns (eight sites for the neighborhood and one for the current agent position). If identical neighborhood patterns exist, we select one of the neighborhoods. These overlapping elements affect the element selection in the next paragraph.

Numbering each neighborhood site (see **Appendix Figure**) enables us to construct a partial order set. Since a partial order set generally never closes with binary operations such as meet and join, this set never constructs a lattice (Davey and Priestelely, 2005). To construct a lattice, we use Dedekind-MacNeille completion (Davey and Priestelely, 2005). Pertinent details from lattice theory are given in **Appendix A and B**. Making a lattice involves constructing a logical relationship, closed under a binary operation, among current, past, and future information.

We then stochastically select an element from the lattice. After selection of an element from the lattice, we next take an ideal from this element and construct a congruence of lattices (Davey and Priestelely, 2005). We applied this method in past research related to topics such as species evolution (Niizato and Gunji, 2013). Roughly speaking, congruence of the lattice means making well-defined groupings on the lattice. This grouping is strongly bound by its lattice structure. We use the group that contains an element of the current information. Since this grouping is also an ordered set, we can certainly pick the top element from this group as a representative element (see upper right of Figure 4). This representative element carries past, current, and future information. Using this method, agents sometimes behave as if they have learned about unlearned situations in the active phase, making the conflict between active and passive phases larger than in ALM.

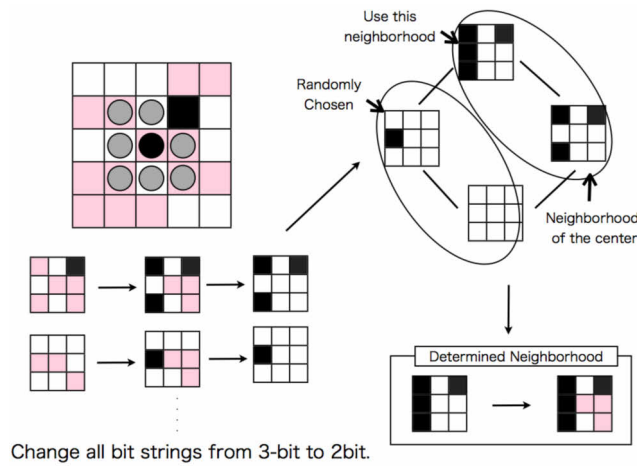

Figure 4: Constructing the lattice. Considering the neighborhood of the neighborhood, we can pick up nine 8-bit strings. The overlapped element will affect the selection of an element, which makes an ideal.

### Sign Making in ALMA

Anticipation of agents contributes to sign making (avoidance sign). We set the environment as in Figure 6 (A). At the center of the boundary, blocks and scent markings are distributed alternately. The first set of scent markings lasts until the end. The region in a given space is divided as Side I and Side II. These blocks prevent free movement between the two sides, but the existence of scent markings attracts agents around the center. In other words, the centerline of this space provides a contradiction for each agent. Do these factors affect the behavior of agents?

To examine the effect of anticipation in this heterogeneous environment, we compare four interaction patterns, namely, the control model, ALM, the control model with anticipation, and ALMA. Figure 5 shows the distribution of the density probability for these four interaction patterns. Obviously, agents of the both of control models (Figure 5 (A) and Figure 5 (C)) concentrate around the blocks, even after many steps have passed. At first glance the behaviors of ALM (Figure 5 (B)) and ALMA (Figure 5 (D)) seem similar, but there is a radical difference between them; in ALMA the density distribution around the centerline is very low compared with ALM and both the control models. This behavior suggests that each agent in ALMA avoids center blocks, and shows territorial behavior in both regions. In other words, each agent in ALMA recognizes a sign of avoidance.

This result is also supported by statistical results (Figure 6(B)). We compared the mean maximum spending time at Side I or Side II with four patterns of interaction (100 times for 100,000 steps). ALMA contains many agents which spend at one side for long time. It is worth to point

Figure 5: The distribution of density probability for four ways of interactions, the control (upper left), ALM (upper right), the control with anticipation (lower left), and ALMA (lower right). The grid is  $30 \times 30$  and the number of agent is 150.

out that there is almost no difference between the models without anticipation (ALM and the control model). This result suggests that anticipation helps agents recognize signs of avoidance. Furthermore, Figure 6 (B) also suggests that learning in the active phase in ALMA plays an important role for sign making. Because there are many collisions around center blocks, the neighborhood in ALMA contains many occupied sites when the agent is in the active phase. However, this is insufficient for sign making. There are too many neighborhood patterns (6560 patterns!), and since there are conflicts among the past, current, and future information, the constructed lattice would tend to make a modular lattice, meaning that each element has many complementary elements (two elements satisfy  $a \vee b = 1$  and  $a \wedge b = 0$ ). High modularity leads to selection of the top lattice element when we apply the congruence method to the lattice. In this sense, agent's anticipation is driving-force for sign-making in heterogeneous environments.

### Collective Cognition in ALMA

In this section, we discuss the possibility of collective cognition in changing environments. Collective cognition is defined here as a collective response against a changing environment. Cognition, including human cognition, inevitably involves the surrounding situation. We sometimes find differences even between situations that seem to be the same. One famous example is Rubin's vase, a black and white optical illusion. Focusing on one color in the illustration, one sees a vase. Focus on the other, and one sees opposing faces instead. The stimulus from viewing this picture must be the

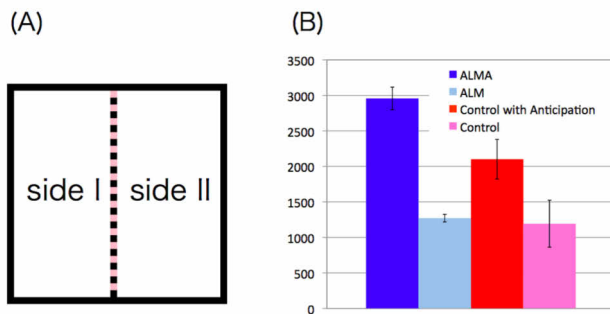

Figure 6: (A) The right side of the center is Side I. The left side of center is Side II. (B) The mean maximum spending time in Side I or Side II. The four bars correspond to the control model (pink), ALM (light blue), the control with anticipation (red), and ALMA (blue).

same, but cognition differs regarding its appearance. Although this is an extreme example, different recognition of the same situation is an essential factor of cognition. Different cognition regarding the same object allows agents multiple interpretations that provoke different reactions against the same object. In this sense, we can discuss an agent's collective cognition in heterogeneous environments.

To examine the possibility of collective cognition in ALMA, we examine the behavior of agents when an environment temporally changes. Here, a changing environment is shown as a changing number of blocks at the centerline, as in the previous section. There are two patterns, additions and subtractions (Figure 7 (A)). Since adding blocks means that blocks suddenly appear in space and removing blocks means gradually removing a wall, these changes are radically different from a cognitive standpoint. We measured the behavioral differences between them as taking the mean density probability around the centerline.

Figure 7 (B) shows the result. The triangles correspond to removed blocks and the rectangles correspond to added blocks. The horizontal line is the rate of blocks in the center, so zero on the horizontal line means there are no blocks in the space. The rate of blocks gradually increases or decreases 0.1 points every 1,000 steps. We performed 100 trials and averaged the value for each block count. Figure 7 (B) suggests that transitions of the density probability are different when adding or removing blocks. The shapes of Figure 7b indicate hysteresis, a property that recalls Harken (1983), a famous study that showed human cognition changes over time.

The density probability around the center gradually decreases with an increased number of blocks. When block rate decreases from 1, however, the density probability drops from 1.0 to 0.5, then increases from 0.5 to 0.0. These differences come from the agent learning in the active phase.

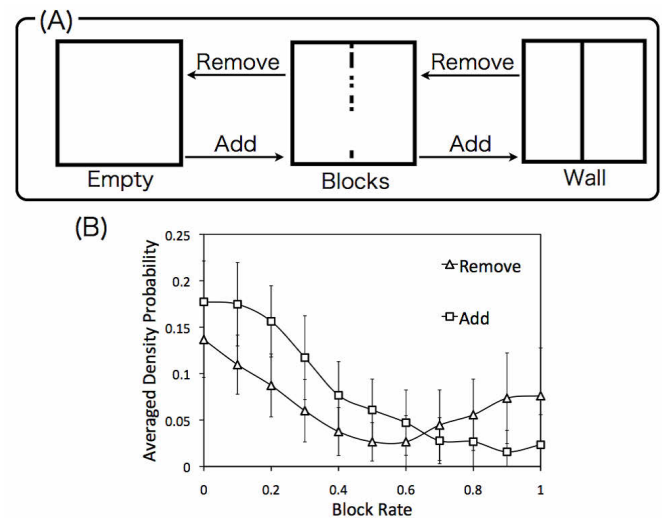

Figure 7: (A) Adding or removing blocks at the center. Three blocks are added or removed every 1,000 steps. (B) The rate of mean density probability around the center with block rates. The triangle corresponds to removing blocks and the rectangle corresponds adding blocks.

Each agent recognizes added blocks as ones that should be interpreted in the active phase. When removing blocks, however, the agent starts to recognize blocks as a part of wall. This wall in itself is not subject to interpretation for each agent, because information about the wall never changes with time. Interpreting blocks as a wall or not a wall changes the agent's behavior.

## Discussion

Self-organization has been discussed by many researchers. To briefly summarize the main assertion of self-organization, it is "simple local interaction that creates global behavior." In real systems, however, this is insufficient to understand emergent phenomena. For example, when we consider the evolution of life, it must have started from simple forms and behaviors. We should therefore ask how simple behaviors evolve into complex ones. A related question would ask about the origin of various higher-layer behaviors. It is considered that the concept of self-organization would answer this question.

However, we have to admit that the concept of self-organization contains a serious problem if we seek the origin of various higher-layer behavior. There are examples even in cellular automata. Class IV automata have computational abilities using patterns of time evolution as particles (Wolfram, 2005). Although Class IV automata can exhibit higher-layer behavior, there is a clear distinction between the system as a device and its modelers. In other words,

the computational property of a cellular automaton never explicitly emerges unless the modelers (or the observer) set the appropriate initial conditions. Even when one high-layer behavior (universal computation in Class IV) emerges, the theory of the self-organization inevitably contains a kind of this problem.

To solve this division problem between the modelers and the systems, we proposed multiplicity of interaction. Introducing multiplicity to simple interaction allows its own interpretation of situation. We notice that multiple interpretations of situations must be distinct from simple hybrid models, which contain many kinds of interactions because the base interaction is consistently single. Having multiple interpretations of a single interaction, the usage of the interaction would be open to many applications without interference from modelers when agents encounter different situations.

In our model, a single interaction corresponds to the attractiveness of scent markers. The multiplicity of interaction was constructed from three factors: asynchronous updating, site pattern learning in the active phase, and anticipation. The latter two concepts originally come from disagreement of timing among agent actions induced by asynchronous updating. Adding the latter two properties, the discrepancy between the active and passive phases becomes larger than the original one. Our model suggests that the discrepancy, induced by asynchronous updating, becomes the driving force of many applications for single interaction in various environments.

We showed that our model could connect various kinds of behaviors, which are sometimes seen as contradictory or irrelevant to each other. First we observed that agents under ALM could search more efficiently than agents under the control model. We discussed that this result had relevance with the ecological searching trade-off problem. Furthermore, agents under ALMA recognize signs of avoidance for the center blocks. Although the behavioral range of agent covers the entire space, each agent avoids the centerline, behaving as if marking territories where they belong. Searching an area means spreading over its entire space. Marking territories means establishing boundaries. These two collective behaviors are qualitatively conflicting, but can be implemented by introducing multiplicity to the interaction without any contradiction. Collective cognition, which we discussed in the last section, is clearly a kind of behavior different from searching behavior. Collective cognition means that agents in ALMA recognize the difference between two ways of changing the environment (adding or removing blocks from the center). Our result suggested that each agent distinguishes between discrete blocks and a wall of blocks.

In this sense, we can conclude that multiplicity of interaction could be open in its usage with various environments. We have confirmed different kinds of global behaviors—searching, sign marking, and collective cognition—by set-

ting various environments using this multiplicity. In other words, to consider how multiplicity of interaction connects the multiplicity of behaviors. If we take this multiplicity of interaction, the degree of the multiplicity would become one possible measure of self-organization of emergent phenomena. Then we can ask the origin of complex behaviors on living systems.

## Appendix A

We briefly introduce the lattice theory for unfamiliar readers of the lattice theory.

**Definition 1 (Partial Order)** Let  $P$  be a set. An order on  $P$  is a binary relation  $\leq$  on  $P$  such that, for all  $x, y, z \in P$ .

- (i)  $x \leq x$

1	2	3
4		5
6	7	8

**Appendix Figure** : The way of numbering the neighborhood.

- (ii)  $x \leq y$  and  $y \leq x$ , then  $x = y$
- (iii)  $x \leq y$  and  $x \leq z$ , then  $x \leq z$

We denote a partially ordered set by the pair,  $(P, \leq)$ . For example, a set of bit (binary) strings can construct a partial order. A bit string  $a_1 a_2 \dots a_n$  is a finite sequence of zero, one ( $a_i \in \{0, 1\}$ ). An order between two bit strings such as  $a_1 a_2 \dots a_n$  and  $b_1 b_2 \dots b_n$  is defined by  $a_1 a_2 \dots a_n \leq b_1 b_2 \dots b_n$  if  $a_i \leq b_i$  for all  $i$ . We use a set of bit strings in this study. However, A partial order is not a lattice. Then we define the meet and the join. We define the join " $\vee$ " and the meet " $\wedge$ " of two elements  $x$  and  $y$  in  $P$ . The join can be defined by  $x \vee y = \sup\{x, y\}$  when it exists. The join can be defined by  $x \wedge y = \inf\{x, y\}$  when it exists. The notation of  $\sup(\inf)$  means the lowest (greatest) upper bound of  $\{x, y\}$  in  $P$ .

**Definition 2 (Lattice)** Let  $(P, \leq)$  be a non-empty partially ordered set. If  $x \vee y$  and  $x \wedge y$  exist for all  $x, y \in P$ , then  $(P, \leq)$  is called for a lattice.

**Definition 3 (Ideal)** Let  $(L, \leq, \wedge, \vee)$  be a lattice. A non-empty subset of  $J$  is called an ideal if

- (i)  $x, y \in J$  implies  $x \vee y \in J$ ,
- (ii)  $x \in L, y \in J$  and  $x \leq y$  imply  $x \in J$ .

**Definition 4 (Congruence on a Lattice)** Let  $(L, \leq, \wedge, \vee)$  be a lattice. Let an equivalence relation on  $L$  be  $\theta = \{< x, y > \in L \times L \mid \text{such that any } x, y, z \in L,$

- (i)  $< x, x > \in \theta$
- (ii)  $< x, y > \in \theta \Leftrightarrow < y, x > \in \theta$
- (iii)  $< x, y > \in \theta$  and  $< y, z > \in \theta \Rightarrow < x, z > \in \theta$

We also denote  $< x, y > \in \theta$  as  $xy \pmod{\theta}$ . Then an equivalence relation is a congruence on  $L$ , if for any  $x, y, z, w \in L$ , ( $x \equiv y \pmod{\theta}$  and  $z \equiv w \pmod{\theta}$ )  $\Rightarrow$  ( $x \vee z \equiv y \vee w \pmod{\theta}$  and  $x \wedge z \equiv y \wedge w \pmod{\theta}$ ).

More detail in Davey and Priestelely in 2005.

**Theorem (Reconstruction of a Lattice from a Quotient Lattice)** Let  $L$  be a lattice and  $f$  be a natural quotient map such as  $f : L \rightarrow L/\theta$ . For the binary relation derived from an ideal  $J \subseteq L$ , there exists a filter  $K \subseteq L$  such that  $[x]_{\theta(J)} = f^{-1}(x)$ , where for any  $x \in K$ ,  $f^{-1}(x) := \downarrow x - \cup_{y \in K, y < x} \downarrow y$

**Proof** See in (Gunji et al., 2006; Niizato and Gunji, 2013).

## Appendix B

To construct the lattice from a partial order set, we use Dedekind-MacNeille completion, as follows: In the partial order set  $P$ , we can take a lower and upper closed set, which we represent as  $P^u$

(upper) and  $P^l$  (lower). The upper set is  $P^u = \{x \mid y \leq x \text{ for any } y \in S\}$ . The lower set  $P^l$  is the dual of  $P^u$ .

**Theorem (Dedekind-MacNeille completion)** For any order set  $P$ , we can construct the set as follows:

$$\text{DM}(P) = \{A \subseteq P \mid A^{ul} = A\}$$

Generally, a set that satisfies  $A^{ul} = A$ , is called a "cut". To understand the meaning of Dedekind-MacNeille completion, the following lemma is useful.

**Lemma** For any ordered set  $P$ , the following statements are satisfied.

- (i) For any  $x \in P$ ,  $(\downarrow x)^{ul} = \downarrow x$ .
- (ii) For any  $A \subseteq P$  and  $\bigvee A \in P$ , then  $A^{ul} = \downarrow (\bigvee A)$ .

## Appendix C

Here we describe the detail of the algorithm of ALM and ALMA. This model consists of  $N$  agents moving in discrete time and in a grid space. Numbering neighbor sites as **Appendix Figure**, we can define 3-bit strings as  $\bar{a} = a_1 a_2, \dots, a_n$ . We also define the neighborhood of the neighborhood in ALMA as eight 3-bit strings  $\bar{b}_1, \bar{b}_2, \dots, \bar{b}_8$ . First, agents are randomly distributed in a given space. The algorithm is constructed as follows.  $i$  is a tag of the agent. Each agent is chosen asynchronously in density dependent.

**For** ( $\exists j \in \{1, 2, \dots, 8\} \mid a_j^i$  is occupied) {  
 $\text{Memo}^i(a^i) = a^i$

Select the moving site from a set  $S$ .

$$S := \{j \mid a_j^i = 0 \text{ or } a_j^i = 1\}$$

The selection probabilities are;

$$\text{Prob}(a_j^i = 0) = \mu / \sum_j \text{Weight}(a_j^i)$$

$$\text{Prob}(a_j^i = 1) = 1 / \sum_j \text{Weight}(a_j^i)$$

}  
**For** ( $\forall j \in \{1, 2, \dots, 8\} \mid a_j^i$  is not occupied) {

**If** (Using ALM) {

$$\bar{a}^i \leftarrow \text{Memo}^i(\bar{a}^i)$$

Select the moving site from a set  $S$ .

$$S := \{j \mid a_j^i = 0 \text{ or } a_j^i = 1\}$$

The selection probabilities are;

$$\text{Prob}(a_j^i = 0) = \mu / \sum_j \text{Weight}(a_j^i)$$

$$\text{Prob}(a_j^i = 1) = 1 / \sum_j \text{Weight}(a_j^i)$$

}

**If** (Using ALMA) {

$$\bar{b}_0^i \leftarrow \text{Memo}^i(\bar{a}^i)$$

Pick up the neighborhood of neighborhood of  $i$ ;

$\bar{b}_1^i, \bar{b}_2^i, \dots, \bar{b}_8^i$  respectively.

**For** ( $0 \leq j \leq 8$ ) {

**For** ( $1 \leq k \leq 8$ ) {

$$\text{If} (\bar{b}_{j,k}^i = 1) \bar{b}_{j,k}^i = 0$$

$$\text{Else If} (\bar{b}_{j,k}^i = 2) \bar{b}_{j,k}^i = 1$$

}

}

Make a partial order set  $P$  from  $\{\bar{b}_0^i, \bar{b}_1^i, \dots, \bar{b}_8^i\}$ .

$$P := \{s_1, s_2, \dots, s_m\}$$

$m (\leq 9)$  is the number of elements of  $P$ .

Count the overlapping elements.

$$Num(s_1) = n_1, \dots, Num(s_m) = n_m$$

Make a lattice  $L$  from  $P$

Using **DM** completion.

$$L = \{s_1, s_2, \dots, s_m, s_{m+1}, \dots, s_{m+l}\}$$

$l$  is the number of adding elements.

Select one element from  $L$ .

The selection probability of each element is,

$$Prob(s_k) = Num(s_k) / \sum_j Num(s_j)$$

Make a congruence by using selected element  $s_k$ .

Then select the top element in the congruence.

Mathematically, when  $J$  is an ideal,

$$s''^i \Leftarrow \bigvee \{s_j \in L | s_j \in [s_0]_{\theta(J)}\}$$

**For** ( $1 \leq j \leq 8$ ) {

**If** ( $s_j'' = 1$  and  $b_j^0 = 1$ )  $a_j^i = 2$

**Else If** ( $s_j'' = 0$  and  $b_j^0 = 0$ )  $a_j^i = 0$

**Else**  $a_j^i = 1$

}

Select the moving site from a set  $S$ .

$$S := \{j | a_j^i = 0 \text{ or } a_j^i = 1\}$$

The selection probabilities are;

$$Prob(a_j^i = 0) = \mu / \sum_j Weight(a_j^i)$$

$$Prob(a_j^i = 1) = 1 / \sum_j Weight(a_j^i)$$

}

$Memo^i(-)$  means the store information about site pattern for each agent  $i$ .  $Num(-)$  means the number of overlapping element in  $\{b_0^i, b_1^i, \dots, b_8^i\}$ .

# Task Allocation Strategy for Time-Constrained Tasks in Robots Swarms

Yara Khaluf<sup>1</sup> and Franz Rammig<sup>1</sup>

<sup>1</sup>Heinz Nixdorf Institut, University of Paderborn, Germany  
{yara, franz}@hni.uni-paderborn.de

## Abstract

Task allocation is a key problem, which has a direct influence on the system performance in all kinds of distributed systems. This paper focuses on a specific kind of task allocation in swarm robotic systems, where the tasks are associated with specific time constraints.

The paper presents a self-organized task allocation strategy, which aims to assign robot swarms to time-constrained tasks in a distributed manner. The robots assignment is performed based on particular specifications including task sizes and deadlines in addition to the specification of the single robot performance on the considered tasks. No central control is required to govern the swarm behaviour and no communication is exploited among robots.

## 1 Introduction

Swarm robotics is a recent field of research that takes inspiration from complex natural systems such as colonies of social insects (ants, honeybees, etc.) or groups of cooperating animals. It is a kind of mobile distributed system with a high density and which can be mainly characterized by its: redundancy, where robots failures do not affect the system functionality, scalability, since the system can be extended by adding robots, and flexibility where it can be used to perform a large spectrum of applications.

In many practical robotics applications the successful execution of a task depends not only on the logical correctness of the operations that robots are performing, but also on the time before which the results are delivered. Such tasks are referred to as real-time tasks and they are generally categorized according to their deadlines into: *hard* real-time tasks, where missing the deadline can lead to catastrophic results and *soft* real-time tasks, where missing the deadline decreases the quality of results. Real-time tasks will be common to encounter as soon as the swarm robotic systems are exported out of the research labs to be involved in real life applications. While dealing with hard-deadlines is beyond the capabilities of a fully stochastic system like swarm robotics, tasks with soft deadlines are the suitable candidates for swarm robotics. This paper discusses real-time tasks with soft deadlines, which need to be performed

by a swarm of homogeneous robots. The goal is to assign the robots to the tasks under their time constraints in a fully distributed and autonomous manner. The proposed allocation strategy neglects initially the influence of physical interferences among robots, on the overall performance of the system. However the strategy can be extended later to include this influence.

The rest of the paper is organized as follows: section 2 reviews the literature of task allocation in swarm robotic systems with and without time constraints. In section 3 a formulation of the task allocation problem under time constraints is introduced. The designed allocation strategy is explained with its different stages in section 4. Section 5 presents a numerical example with its Monte-Carlo simulations to illustrate the steps of the allocation strategy and verify it. In section 6 a swarm robotic scenario is introduced where the allocation strategy is applied and simulated. The paper is concluded in section 7.

## 2 Related Work

Task allocation can be found in nature such as in ant and bee colonies Bonabeau et al. (1998). Mathematical models of task allocation, which focus on simple reactive mechanisms and study the fraction of robots engaged in a particular task as a function of the number of available tasks as perceived by the robots, were performed like Lerman et al. (2006). The task allocation solutions proposed in the literature can be classified in three broad categories: *centralized*, *negotiation-based* and *self-organized*: centralized techniques assume the presence of a central coordinator responsible for the allocation of the agents to the tasks. Self-organized systems, on the contrary, are constituted by peers that take decisions autonomously, with limited negotiations with other peers and without a central point of control. This kind of systems are generally less prone to catastrophic failures and considered a better approach when rapid adaptation to changes in the environment is required. Most of these studies tackle simple problems without task interdependencies, Dahl et al. (2009). Negotiation-based approaches, generally based on auction-based strategies, are the compromise solution be-

tween centralized and self-organized systems, Dias et al. (2005), Gerkey and Mataric (2002), Zheng et al. (2006). In auction-based strategies, the robots bid on the announced task according to specific task characteristics and to their relative capabilities. One of the characteristics that is often criticized in this approach, is that many negotiation-based solutions assume a fully connected network among the robots, which is not the case in many realistic applications. A comparison between the auction-based approaches and the self-organized ones based on threshold can be found in Kalra and Martinoli (2006). A general taxonomy of task allocation strategies in robotic systems has been presented in Gerkey and Mataric (2004) along three main comparisons: *single-task robots (ST)* vs. *multi-task robots (MT)*, where single and multiple robots are able to perform only one task at time; *single-robot tasks (SR)* vs. *multi-robot tasks (MR)*, where each task needs one robot or more, and the *instantaneous assignment (IA)* vs. *time-extended assignment (TA)* where it is assumed that the robots and the environment allow only for an instantaneous task allocation with no future planning.

In swarm robotics, response-threshold mechanisms are relatively common Nouyan et al. (2005), Nouyan et al. (2004), Ducatelle et al. (2009b), Ducatelle et al. (2009a), Krieger and Billeter (2000). In this approach, each robot is programmed to react to stimuli associated to the different tasks. Agassounon and Martinoli (2002) introduce a task allocation for the traditional swarm task "foraging". Another threshold-based algorithm for allocating workers to a given task whose demand evolves dynamically over time is presented in Agassounon et al. (2001). In Liu et al. (2007) a mathematical model for a similar task allocation behaviour is introduced. Some works combine the common swarm response-threshold approach with a kind of communication protocol to avoid the need for a central unit as in Zhang et al. (2007). A very few works to our best knowledge, have assumed a target distribution for the robots over all the available tasks to be reached like we can find in McLurkin and Yamins (2005). Few authors have studied the problem of task allocation in swarm robotic systems with time constraints associated to tasks. Some of the performed studies were based on the auction techniques for the allocation in respect to deadlines like in Guerrero and Oliver (2010) and Guerrero and Oliver (2011). Other works like Acebo and Rosa (2008), have introduced a heuristic based on the so-called Bar-System model, where the key idea is to simulate the way waitresses assign themselves to bar customers in an efficient and distributed way. The approach is then applied to a group of loading robots for a commercial harbour. In Schneider et al. (2005) and Jones et al. (2007) market-based task allocation strategies, where time is the critical constraint, are considered together with a reward mechanism associated to a task being successfully completed.

### 3 Problem Formulation

The problem of autonomous task allocation in presence of deadlines can be formulated as follows: a swarm of  $N$  robots should be allocated to a set of  $m$  tasks  $\{T_1, \dots, T_m\}$ . The task deadlines  $\{D_1, \dots, D_m\}$  and the task sizes  $\{S_1, \dots, S_m\}$ , are assumed to be known a priori. The task is assumed to be built up of individual parts, where the robot can accomplish one part per time. The size of any task represents the discrete number of parts which should be accomplished within the task deadline. Each task  $T_i$  is composed of  $S_i$  parts and accomplishing  $T_i$  is achieved by accomplishing all of its  $S_i$  parts. The real-time tasks we consider in our study have soft deadline and require to be executed in parallel. The switching costs between them are negligible in comparison to the task deadlines. The system is designed as a fully autonomous one, where no communication among robots is applied and no central unit is used for the allocation purposes.

The single robot performance on a specific task is expressed in terms of the random time required by the robot to accomplish one part of the considered task. The random variable associated with the single robot performance is modelled in this paper as a normal distributed variable with a task-specific mean and a task-specific standard deviation. The single robot performance is an essential input for the developed allocation strategy. Robots can measure their individual performances by working on each of the considered tasks for a specific period of time, registering the times they require to accomplish individual parts and estimate the mean and standard deviation related to their performance on each task. Tasks are served according to their priorities, which are derived based on the task deadlines. The task with a shorter deadline has a higher priority to be executed. Before starting the execution, a list of the  $m$  tasks with their sizes and deadlines is provided to the swarm. These task specifications in addition to the single robot performance on the different tasks are the inputs used later to perform the tasks allocation.

We concentrate in this paper on a kind of *dynamic* task allocation, where the robot is allowed to stay on the same task or to switch to another one. The switching decision could be taken each time the robot finishes working on a part of the current task or at specific time points. Switching at specific time points, during the execution times of the tasks, requires global synchronization among the robots to take the decision at the specified time point. Dynamic task allocation is useful to be applied in many applications, where the switching costs among tasks can be considered being negligible. Such cases can be encountered when the tasks occupy a shared physical arena, so robots do not need to travel among them while switching. An example is foraging multiple kinds of objects where each kind represents an individual task and all kinds are scattered on the same arena. Another possibility to omit switching costs, is when they are negligi-

ble in comparison to the task deadlines.

The selection of the next task is performed by means of allocation probability matrices, which are calculated based on the task specifications and the single robot performance. The probability matrices are of the form  $P_{ij}$ , which represents the probability to switch to task  $T_j$  from task  $T_i$  while the switching costs are negligible in comparison to the deadlines.

#### 4 Robot Allocation Strategy

The goal of this study is to develop a feasible task allocation strategy that allows robots to assign themselves autonomously to a set of real-time tasks with respect to the task deadlines. In a fully stochastic system like swarm robotics where even the performance of a single robot on a specific task represents a stochastic variable, it is particularly difficult to develop an allocation strategy which can guarantee the execution of the task within its deadline.

Our strategy attempts to find an optimal number of robots to be assigned to each task based to the size and deadline of the task in addition to the performance of the single robot on that task. The required number of robots on each task is used to derive allocation probability matrices, which are used by the robots to allocate themselves autonomously to the tasks during their execution.

Each task is considered to be "inactive" as soon as it is completely accomplished or when its deadline is exceeded, otherwise the task is considered as "active". Robots are not required to be assigned to inactive tasks. Consequently, the number of robots available for allocation changes based on the current number of active tasks. In order for the allocation strategy to exploit the current number of robots available for allocation, the time between the start of tasks execution and the largest deadline, is divided into periods:  $\{\pi_1, \dots, \pi_m\}$  where:

$$\pi_i = D_i - D_{i-1} \quad \forall i \in \{2, \dots, m\} \quad (1)$$

The first period has the length of the earliest deadline  $\pi_1 = D_1$ . Figure 1 illustrates the periods and the active tasks within each period.

Figure 1: Active tasks over the defined periods

#### 4.1 Required Number of Robots

The single robot performance on task  $T_i$  is expressed, as mentioned above, in terms of the time required by a single robot to accomplish one part of task  $T_i$ . This random time is modelled as a normally distributed variable with the mean  $\mu_i$  and the standard deviation  $\sigma_i$ . Let us use  $k_i$  to denote the number of parts which could be accomplished by a single robot on task  $T_i$  within its deadline  $D_i$ . The value of  $k_i$  is taken within the discrete range  $[0, +\infty[$ , which represents the possible outcomes related to the number of parts could be accomplished by a single robot within  $D_i$ . Let us define the event  $E_i(k_i)$  that a single robot accomplishes  $k_i$  parts on task  $T_i$  within  $D_i$ . We refer to the time spent by a single robot to accomplish  $k_i$  parts by  $\tau_i(k_i)$ , then we have the following two events equivalents:

$$E_i(k_i) \iff \tau_i(k_i) \leq D_i \quad (2)$$

The probabilities of the equivalent events in Eq. (2) are equal and they represent the probabilities we are interested in:

$$\Pr(E_i(k_i)) = \Pr(\tau_i(k_i) \leq D_i) \quad (3)$$

As the time spent by the robot to accomplish *one* part of task  $T_i$  is normally distributed with the mean  $\mu_i$  and the standard deviation  $\sigma_i$ , the right side of Eq. (3) is the probability that the sum of  $k_i$  random variable, each one being distributed using  $Norm(\mu_i, \sigma_i)$ , is smaller than or equal to  $D_i$ . It is well known that the sum of  $n$  random variable each one being distributed with  $Norm(\mu, \sigma)$ , is a random variable distributed normally with the mean  $n\mu$  and the standard deviation  $\sqrt{n}\sigma$ . Consequently, the probability  $\Pr(\tau_i(k_i) \leq D_i)$  in Eq. (3) represents the cumulative density function CDF of the normal distribution with the mean  $k_i\mu_i$  and the standard deviation  $\sqrt{k_i}\sigma_i$ .

$$\Pr(\tau_i(k_i) \leq D_i) = \frac{1}{2} [1 + \operatorname{erf}(\frac{D_i - k_i\mu_i}{\sqrt{2k_i}\sigma_i})] \quad (4)$$

The allocation strategy applies the cumulative density function in Eq. (4) to find out the probability associated with the event  $E_i(k_i)$  for each  $k_i \in [0, S_i]$ , where  $S_i$  is the size required to be accomplished on  $T_i$  within  $D_i$ . This probability  $P(E_i(k_i))$  is referred to as the success probability of the event  $E_i(k_i)$ . The events  $E_i(k_i)$  are distributed following a binomial distribution with the success probabilities  $P(E_i(k_i))$ , see Figure 2.

The expected value of a random variable  $X$  which is distributed according to a binomial distribution with  $n$  trials and the success probability  $p$  is given by:

$$E[X] = np \quad (5)$$

We map the number of trials  $n$  to the required number of robots, where each robot can accomplish  $k_i$  parts with a success probability  $P(E_i(k_i))$ . In order to find the required size

Figure 2:  $E_i(k_i)$  for each  $k_i \in [0, S_i]$  with the success probability associated to each of  $k_i$  values

of trials (number of robots), such that one robot of the  $n$  robots is expected to accomplished  $k_i$  parts within  $D_i$ , we substitute the expected value by 1 and the success probability by  $P(E_i(k_i))$  in Eq. (5), so we have:

$$1 = n_i P(E_i(k_i)) \implies n_i = \frac{1}{P(E_i(k_i))}$$

$n_i$  is the number of robots required to achieve an expected number of accomplished parts equal to  $k_i$  within  $D_i$  by one robot. However, we aim to achieve an expected number of accomplished parts equal to  $S_i$  within  $D_i$ , hence the required number of robots is calculated using the following equation:

$$N_i = \lceil \frac{n_i S_i}{k_i} \rceil \quad (6)$$

Let us consider the example of one task with the size  $S_i = 10$  parts, the deadline  $D_i = 10$  time units. The single robot performance on this task in terms of the time required by the single robot to accomplish one part, is normally distributed. We assume different means of the random time:  $\mu_i \in \{2, 4, 6\}$  and a unique standard deviation  $\sigma_i = 0.01$ . The number of parts  $k_i$ , which could be accomplished by a single robot within  $D_i$  can takes its value in  $[0, 1, \dots, +\infty]$ . However the range of interest is  $k_i \in \{0, 1, \dots, 10\}$ . Each event  $E_i(k_i)$  of accomplishing  $k_i$  parts by a single robot is associated with a probability calculated using Equation (4). Figure 3 shows the different values of  $k_i$  with their success probabilities calculated for the different means. We consider the mean  $\mu_i = 2$  for the rest of the example. Figure 4 shows how the required size of trials  $n_i$  changes with changing  $k_i$ .  $n_i$ , represents the size of the robots needed to have on average one robot accomplishing  $k_i$  parts within  $D_i$ . In the same figure we can see the total number of robots  $N_i$  required by task  $T_i$  calculated for each  $k_i$  value.

#### 4.2 Optimal Robot Number and Allocation Probability Matrices

In the previous section the allocation strategy calculates the required number of robots  $N_i$ , which should be assigned to task  $T_i$  to accomplish  $S_i$  parts on average within the deadline  $D_i$ . There exist several possible number of robots  $N_i$  to be used. Each value of the  $N_i$  is associated with a unique value

Figure 3: The relation between the number of parts could be accomplished by a single robot within the deadline and its probability of success

Figure 4: The relation between the number of parts  $k_i$  and the number of required robots in trials  $n_i$  and by the task  $N_i$

of parts,  $k_i$ . The process starts by finding the success probability related to each event  $E_i(k_i)$ , where  $k_i \in \{0, \dots, S_i\}$ . After that, the size of the trials (robots), which is required to have on average one robot accomplishing  $k_i$  parts within  $D_i$ , is determined. Finally the total number of required robots is calculated using Equation (6).

However, a robot swarm represents a limited resource with a given size, which applies a strict constraint on selecting the feasible number of robots  $N_i$ , could be assigned to each of the active tasks during period  $\pi_j$ :

$$\sum_{i=j}^m N_i \leq N \quad (7)$$

where  $N$  is the size of swarm used in the solution.

The developed strategy attempts to minimize the number of robots required by each task individually. Assigning the minimum of the feasible numbers of robots, reduces the impact of potential physical interactions and save robotic resources from unnecessary use. In addition, it provides a

higher chance to schedule newly arrived tasks. Hence, the allocation strategy aims to minimize, for all tasks, the objective function introduced in Eq. (6) under the constraint of Eq. (7) and consequently to find the optimal number of robots for any task  $T_i$ :

$$N_i^{opt} = \min(\lceil \frac{n_i}{k_i} S_i \rceil) \quad (8)$$

The optimal number of robots is the robots number, which the allocation strategy aims to assign to each task though all the periods where this task is active. However, as the swarm size is limited to  $N$  robots, it is possible to not have enough robots in order to assign  $N_i^{opt}$  to task  $T_i$  over all its active periods. The allocation strategy starts, for each period, to satisfy the robot needs of the tasks according to their priorities, which are based on their deadlines. Lack of robots can occur on task  $T_i$  at any of its periods and this robot lack leads, in turn, to a lack in the amount of work was planned to be accomplished by the  $N_i^{opt}$  robots on task  $T_i$  within the considered period. Let us denote the missed number of robots on task  $T_i$  within the period  $\pi_j$  by  $\delta_i(\pi_j)$ . This number of robots was missed to work on task  $T_i$  within the time  $\tau(\pi_j)$ , which is the length of period  $\pi_j$ . We introduce the term of *robots lack density* to refer to the lack of robots happened over a specific period of time like  $\tau(\pi_j)$ . Let us denote the lack density happened on task  $T_i$  during period  $\pi_j$ , by  $\alpha_i(\pi_j)$ . This lack density can be calculated as in following:

$$\alpha_i(\pi_j) = \delta_i(\pi_j) \tau(\pi_j) \quad (9)$$

The lack density associated with all robot lacks, which happened on task  $T_i$  up to period  $\pi_j$  is denoted by  $\alpha_i^{\pi_j}$  and represents the sum of the lack densities over all the task periods up to  $\pi_j$ :

$$\alpha_i^{\pi_j} = \sum_{k=1}^{j-1} \delta_i(\pi_k) \tau(\pi_k) \quad (10)$$

The goal now, while finding out the required number of robots to be assigned to task  $T_i$  during period  $\pi_j$ , is to cover the robot lacks happened on task  $T_i$  up to period  $\pi_j$ . The needed number of robots to cover the lacks that happened on  $T_i$  up to period  $\pi_j$ , should be scaled based on the length of  $\pi_j$ . The sum of lack densities associated with the previous periods is used to find out the number of robots,  $\delta_i^{\pi_j}$ , required to cover the lacks of the previous periods:

$$\delta_i^{\pi_j} = \lceil \frac{\alpha_i^{\pi_j}}{\tau(\pi_j)} \rceil \quad (11)$$

Finally, the allocation strategy can calculate the number of robots required to be assigned to task  $T_i$  during period  $\pi_j$  like follows:

$$N_i(\pi_j) = \begin{cases} N_i^{opt} + \delta_i^{\pi_j} & \text{if } N_{current} \geq N_i^{opt} + \delta_i^{\pi_j} \\ N_{current} & \text{if } N_{current} < N_i^{opt} + \delta_i^{\pi_j} \end{cases} \quad (12)$$

After calculating the number of robots to assign to each task over the periods where the task is active, the allocation strategy outputs a set of probability matrices associated with the defined periods. These matrices are used for the dynamic allocation of the robots. Robots use the probability matrix of the current period to allocate themselves to the tasks: each time a robot finishes working on one part of the current task, or at the beginning of current period all robots allocate themselves to the active tasks using the matrix of the period. This dynamic allocation is a self-organized process, as no central unit controls the robots for assignment. The allocation probability  $P_i(\pi_j)$  of task  $T_i$  in period  $\pi_j$  will be then calculated using the following equation:

$$P_i(\pi_j) = \frac{N_i(\pi_j)}{\sum_{k=j}^m N_i(\pi_k)} \quad (13)$$

where  $P_i(\pi_j)$  is the probability to switch from any task to task  $T_i$  in period  $\pi_j$ .

## 5 Numerical Example

We introduce in this section a numerical example to illustrate the mechanism of the developed allocation strategy. Let us assume to have a set of 5 tasks  $\{T_1, T_2, T_3, T_4, T_5\}$  with the soft deadlines  $\{30, 90, 150, 250, 500\}$  and the sizes  $\{1000, 2000, 3000, 4000, 5000\}$ . A homogeneous swarm of  $N = 400$  is used to execute the tasks, where the performance of any individual robot belonging to this swarm on each task is normally distributed with a task-specific mean  $\mu_i$  and a task-specific standard deviation  $\sigma_i$ . For our example the means of the single robots performance on the 5 tasks are as following  $\{2, 3, 4, 2, 6\}$  and the standard deviations are  $\{0.2, 0.3, 0.1, 0.01, 0.5\}$ .

The possible outcomes in terms of task parts, which could be accomplished by a single robot within the deadline on the different tasks, are:  $k_1 \in \{0, 1, \dots, 1000\}$ ,  $k_2 \in \{0, 1, \dots, 2000\}$ ,  $k_3 \in \{0, 1, \dots, 3000\}$ ,  $k_4 \in \{0, 1, \dots, 4000\}$ ,  $k_5 \in \{0, 1, \dots, 5000\}$ . Each event  $E_{k_i}$  of accomplishing  $k_i$  parts by a single robot on task  $T_i$  is associated with a success probability, that is calculated using Equation (4).

The allocation strategy selects the minimum number of robots to be assigned to each of the considered tasks during the periods where the tasks are active:

$$T_1 = 72 \quad T_2 = 72 \quad T_3 = 82 \quad T_4 = 33 \quad T_5 = 62$$

The sum of the required robots numbers is verified against the constraint in (7):

$$72 + 72 + 82 + 33 + 62 \leq 400$$

The lack of robots may occur on any of the 5 tasks is 0 over all periods, as the swarm size is large enough to cover their

robot needs. Hence, the required number of robots to be assigned to task  $T_i$  on any of its periods is given by:

$$N_i(\pi_j) = N_i^{opt}$$

The probability to apply by each robot for assigning itself to task  $T_i$  during period  $\pi_j$  is given by:

$$P_i(\pi_j) = \frac{N_i(\pi_j)}{\sum_{k=j}^m N_i(\pi_k)} = \frac{N_i^{opt}}{\sum_{k=j}^m N_k^{opt}}$$

Thus, the probability matrices over the 5 periods are as in following:

Period  $\pi_1$ :

$$\begin{pmatrix} P_1(\pi_1) & P_2(\pi_1) & P_3(\pi_1) & P_4(\pi_1) & P_5(\pi_1) \\ 72/321 & 72/321 & 82/321 & 33/321 & 62/321 \end{pmatrix}$$

Period  $\pi_2$ :

$$\begin{pmatrix} P_1(\pi_2) & P_2(\pi_2) & P_3(\pi_2) & P_4(\pi_2) & P_5(\pi_2) \\ 0 & 72/249 & 82/249 & 33/249 & 62/249 \end{pmatrix}$$

Period  $\pi_3$ :

$$\begin{pmatrix} P_1(\pi_3) & P_2(\pi_3) & P_3(\pi_3) & P_4(\pi_3) & P_5(\pi_3) \\ 0 & 0 & 82/177 & 33/177 & 62/177 \end{pmatrix}$$

Period  $\pi_4$ :

$$\begin{pmatrix} P_1(\pi_4) & P_2(\pi_4) & P_3(\pi_4) & P_4(\pi_4) & P_5(\pi_4) \\ 0 & 0 & 0 & 33/95 & 62/95 \end{pmatrix}$$

Period  $\pi_5$ :

$$\begin{pmatrix} P_1(\pi_5) & P_2(\pi_5) & P_3(\pi_5) & P_4(\pi_5) & P_5(\pi_5) \\ 0 & 0 & 0 & 0 & 62/62 \end{pmatrix}$$

We simulate the behaviours of the robots using a Monte-Carlo simulation which was repeated 500 times for the tasks specified in the example above. We assume a global synchronization among the robots. Thus, the allocation probability matrices calculated above, are used by robots each at the beginning of its related period to allocate themselves to the tasks during the whole period. Figure 5 shows a comparison between the average of the total number of parts accomplished by the swarm on each of the 5 tasks and the task size.

## 6 Robotic Scenario

In this section we introduce a multi-task scenario where a homogeneous swarm of simple robots is used to work on a multi line production system. In the considered system, different kinds of objects, which are located initially in objects repositories, Figure 6, should be transported to their production areas. We assume 3 arenas of different sizes, where the robot swarm is used to accomplish the transportation tasks on the different arenas. Each arena is associated with a task of transporting a specific number of objects from their repositories to their production area within a specific deadline. The task sizes are:  $\{70, 90, 110\}$  objects and the task deadlines are:  $\{30000, 50000, 90000\}$  time units, where each time unit in our simulation represents 1/10 of a second. The total size of the used swarm is  $N = 20$

Figure 5: A comparison between the average of accomplished parts resulted from 500 repeat of Monte-Carlo simulation with the task sizes

robots and the distance between the objects repository and the production area is for the left arena: 12 meters, for the middle arena 17 meters and for the right arena 23 meters. The robots are scattered initially in a robot repository

Figure 6: Multi-production scenario

tory and as soon as the task execution starts, robots use the designed probability matrices to allocated themselves to the different tasks. They start to transport the objects between their repositories and their production areas moving on separated tracks, where each track can be used by only one robot at a time. Applying the track system reduces the physical interferences between robots and allows to consider them as negligible. The only interferences present are those between the robot and its track boarders and among robots while using the robot repository area to pass to another working areas. The production areas are marked with lights to attract the robots towards them, while transporting the objects. The robots apply a *light\_attraction* behaviour combined with an *obstacle\_avoidance* while transporting the objects to their production areas and a *light\_repulsion* behaviour combined with *obstacle\_avoidance* while travelling

to fetch the objects. The simulator, <sup>1</sup>ARGoS Pinciroli et al. (2012), has been used to simulate the scenario, to measure the single robot performance and to calculate the average of the swarm performance on the 3 considered tasks. The sin-

Figure 7: The probability distribution of the single robot performance on the 3 considered tasks

gle robot performance is modelled, like mentioned above, as a normally distributed random variable with a task-specific mean and a task-specific standard deviation. In our scenario, the single robot performance was measured via repeated high-level simulations in ARGoS in order to characterize the average time required by the single robot to transport one object on each of the 3 tasks. Figure 7 shows the probability density function associated with the single robot performance on each task. The measured means and standard deviations of this performance are as in following:  $\mu = \{2238, 3297.7, 4482\}$ ,  $\sigma = \{427.44, 576.69, 1071.9\}$ . The allocation strategy finds the optimal numbers to be assigned to each of the 3 tasks within their deadlines following the steps explained in section 4. The optimal number of robots to be assigned to the tasks are as following:

$$N_1 = 6 \quad N_2 = 7 \quad N_3 = 7$$

The sum of the required robots is equal to the swarm size  $N = 20$  robots, thus the need of each task will be fulfilled over all the periods where the task is active. The allocation probability matrices are calculated following Equation (13) and are as in following:

Period  $\pi_1$ :

$$\begin{pmatrix} P_1(\pi_1) & P_2(\pi_1) & P_3(\pi_1) \\ 6/20 & 7/20 & 7/20 \end{pmatrix}$$

Period  $\pi_2$ :

$$\begin{pmatrix} P_1(\pi_2) & P_2(\pi_2) & P_3(\pi_2) \\ 0 & 7/14 & 7/14 \end{pmatrix}$$

<sup>1</sup>ARGoS is a discrete-time physics-based simulation framework developed within the Swarmanoid project. It can simulate various robots at different levels of details, as well as a large set of sensors and actuators

Period  $\pi_3$ :

$$\begin{pmatrix} P_1(\pi_3) & P_2(\pi_3) & P_3(\pi_3) \\ 0 & 0 & 7/7 \end{pmatrix}$$

In this robotic example, we assume no global synchronization among the robots. Thus, we allow each robot to use the probability matrix related to the current period, each time it finishes transporting one object in order to select its next task. The fraction of robots, which is not needed in the current period, is kept idle in the robots repository.

We repeat the simulation for 10 times before calculating the average number of transported objects on each task. Figure 8 shows the comparison between the average numbers of accomplished parts on the tasks and their sizes. The small difference we can notice in Figure 8 between the number of transported parts and the number of parts required to be transported on task  $T_1$  is based on the differences of the inter-intervals of robots decisions. As robots are allowed to select their tasks each time they finish transporting one object, so the time point of the decision is based on the mean  $\mu_i$  and the standard deviation  $\sigma_i$  of the single robot performance on the considered task  $T_i$ . Hence, robots working on a specific task may be faster in taking their switching decisions than others working on other tasks, which risks keeping the robots fractions as required on all tasks over time. This is one of the weak points of allowing a dynamic switching decision each time the robot accomplishes one part of its current task. However, its effect is strongly related to the differences among the performances of single robot on the different tasks. In addition, it is necessary to use this kind of dynamic decisions, when no synchronization is available among robots to synchronize their decision points with the beginning of each period.

Figure 8: The Comparison between the average number of transported objects on each task and the task size

## 7 Conclusion

In this paper, we have introduced a novel task allocation strategy for swarm robotic systems in context of real-time tasks with soft deadlines. The developed strategy is a fully-

autonomous one, that uses the tasks sizes, deadlines and the single robot performance on the considered tasks to output a set of allocation probability matrices. The resulting matrices are used by the robots, independently through the execution, to allocate themselves to the different tasks with the goal of executing them within their deadlines. The considered swarm is a homogeneous one, where no communication is exploited among robots. The developed allocation strategy is a dynamic one, where robots are allowed to switch among the tasks during their execution times. This kind of dynamic allocation offers several advantages including: the possibility to cope with non-predicted lack in performance and the ability to consider on-line arrival of tasks. However it requires to assume negligible switching costs among the considered tasks. A numerical example of the allocation strategy in addition to a robotic scenario were introduced, where the allocation probability matrices were derived to be used by individual robots in a set of simulations to verify the desired swarm performance. In the future work, the impact of physical interferences on the performance on the single robot could be taken into account while estimating this performance. Considering the influence, the physical interferences has on the performance, leads to more accurate analysis of the allocation.

## Abstract

Here, a conceptual modeling formalism is proposed for the description and study of living and life-like systems. It is based on the real life and evolution of biological organisms and ultimately the system framework is determined by two functions, reproduction and survival – the two main fitness components of natural life. In the simplest form the model is a formal description of a discrete reproduction-survival state-transition system. The initial structure of the model can evolve to become more complex and it holds inherent potential for producing numerous variations of the basic theme. It is proposed, that this modeling formalism provides abstract system basis and immediately applicable conceptual tools for holistic study of living organisms on multiple levels of organization, and thereby for the understanding life and organization of complex living systems from a common systems point of view. The modeling principle is very generic and may therefore be applied directly also to the study of engineered and artificial systems.

## Systems View

The concept of an organism as a prototypic “living thing” is very intuitive for humans. But understanding life in formal terms remains a great challenge for modern science. The immense diversity and complexity of biological organisms has made it difficult to find general answers as to what the “laws of living systems” may be and how they relate to the laws of physics and chemistry. Currently there is neither commonly approved scientific vocabulary nor practical conceptual tools for forming uniform descriptions of life and living systems.

For a long time, the development of a general formalism was perhaps not considered to be an absolute necessity in biosciences. Research progressed very well also in its absence resulting in great scientific and technological breakthroughs. In the modern world, however, the concept of life is extending with increasing force to different kinds of human-made realms. Examples include topics such as artificial life, robotics, engineered minimal cells and the design of nanoscale biomolecular production plants; There are algorithmic information-based evolving systems operating in commerce, traffic, and business, only to mention some. Researchers in many different fields currently find themselves pondering what is the essence of life and living. The question is: How do

artificial and engineered systems and their properties relate to the prototypic biological organisms and natural life? How to test their “life-likeness” and living potential? How to predict the evolutionary trajectories of organism-like or life-like innovations that may reside outside the biochemistry-based internal world of cells and organisms, or even be completely information-based?

## Lists of Life

Currently, a typical way to define life is to form a list of properties that a system should have in order to be classified as living one. For example, Farmer and Belin (1990, 1991) proposed the following list of properties admitting at the same time that any such list is bound to be both imprecise and incomplete:

1. Life is a pattern in space-time, rather than a specific material object.
2. Self-reproduction.
3. Information-storage of self-representation.
4. A metabolism which converts matter and energy from the environment into the pattern and activities of the organism.
5. Functional interactions with the environment.
6. Interdependence of parts.
7. Stability under perturbations and insensitivity to small changes, allowing the organism to preserve its form and continue to function in a noisy environment.
8. The ability to evolve.

Another list (Koshland, 2002) provides seven key principles as basis for life:

1. Program.
2. Improvisation.
3. Compartmentalization.
4. Energy.
5. Regeneration.
6. Adaptability.
7. Seclusion.

These two examples already demonstrate that terminology is neither universal nor self-explanatory: No two terms are the same, yet some clearly point to the same direction. These kinds of lists also need to be accompanied by a discussion on how to interpret them and to apply them to different situations.

Overall, the lists reveal what might be the essence of the problem in terms of describing life and living systems. They are clearly complementary rather than competitive in nature. This can be seen to reflect the difficulty of making a distinction between essential and derived properties when it comes to defining the concept of life. The current situation is therefore, that *not only is life itself an enormously complex phenomenon, but also the many ways in which it is being defined and discussed in the scientific discourse* add an extra layer of conceptual complexity to the problem of dealing with it. This is far from the precision by which physical and chemical concepts can be used to describe and define phenomena in their respective fields.

Here, I take these contemplations further and propose a modeling approach that can be used to determine, define, and combine attributes of life in a more precise and orderly manner.

### Minimal Model Approach

The life and structure of living organisms can be addressed on multiple levels of organization, from molecules to ecosystems. Therefore, the task of choosing an appropriate level of observation is of central importance here – as always when modeling complex phenomena (Checkland, 2000, Flood and Carson, 1993). My solution is a two-step approach: First, only unicellular life is considered. The reason is that despite all the diversity and complexity of biological organisms, their basic constituent unit is the cell. Real unicellular organisms also demonstrate that a single cell can also be an entire organism. This starting point reduces the initial complexity of the modeling problem providing a rather precise entry point to the overall challenge of modeling organisms in general.

Then, by comparing the resulting minimal model view of unicellular life to what is generally known about real, more complex forms of cellular life, including the structure, function, and evolution of different kinds of life cycles and multicellular organisms (plants, animals, and fungi), it is possible to propose how they too can be modeled within the same principle formalism.

### System Outline

In the study of life and living organisms it is typical to focus on mature forms of actively living cells and organisms when they use energy to perform all kinds of functions. For example they can grow, move, produce many kinds of metabolites, respond to stimuli, interact and reproduce. It is also typical to assume that if an organism cannot perform these activities, it will die. However, many kinds of unicellular organisms clearly demonstrate that is not necessarily the case. Although the metabolically active reproducing form is the one that is usually studied, these organisms are often able to alter their appearance completely in order to adopt an alternative form of

existence as some kind passive inert survival structures. An example of this could be the formation of bacterial spores (Morita 1990), fungal spores, or seeds of flowering plants.

Cells of real unicellular organisms do not appear to abandon active state haphazardly. Instead the required cell-developmental changes and events are a response elicited by environmental clues that signal imminent or immediate energy deprivation (see for example the introduction in Hadany and Otto, 2007). It is typical, that once the transformation is complete the organism can withstand extreme conditions that would be destructive to the actively living form. The spore germinates when the environment again improves, and the organism returns to the active state of existence.

Based on this I propose the following minimal formalism for describing unicellular life (summarized in Figure 1). There are two states in which the conceptual living system (cell or organism) can exist. When conditions are favorable, the organism is in the *active state* and it comprises all the typical functions of metabolically active cellular life. *Reproduction* is considered to be an output function of active state living. Maintaining this state requires energy and the cell must obtain it from the environment or from its own internal energy stores. If the cell runs out of energy while it is in the active state, it will die.

Figure 1: Minimal model formalism of living systems, based on unicellular life of real biological organisms. There are two states in which the system can exist. In the active state the system can use energy and nutrients for metabolically active living, growth, and reproduction. Formally the active state has two alternative system outputs: Reproduction (circular arrow) replicates the system without altering its state whereas survival transition takes the system into survival state. Both events require some amount of time and energy to be complete. The organism's state transition dynamics are regulated by energy availability.

The system can perform a *survival transition* when its environment turns hostile. This takes it from the active state to *survival state*. Real unicellular organisms must undergo changes in their appearance and behavior and gene expression profiles must be altered to complete this state-change successfully. In accordance with this the formal transition process assigned to require some amount of time and energy to be complete. Any additional time and energy that the system may need for returning to the active state after entering survival state simply add to the initial cost of initiating a survival transition in the first place. The minimal model survival transition is assigned to be discrete and irreversible: Once initiated, the system's only viable alternative is to enter survival state successfully.

The survival state encloses the organism's defining information content, protecting and conserving it. The

survival state can be maintained without using energy and theoretically it provides indefinite passive existence for the living system in question. The survival state is named after the only system function it provides for the organism, which is mere survival in the sense that the defining information of the organism remains in existence, albeit in an inactive form for the time being.

## The Opposite Ends of Life

In this systems formalism reproduction and survival functions define two ultimately opposite alternatives for the way in which a living organism can remain in existence. An organism that relies entirely only on reproductive active-state living corresponds to a biphasic system case where the probability for entering survival state is zero. A hypothetical example is a unicellular marine alga that exhibits no survival state in its life cycle but instead, all cells are metabolically active reproducing entities that die if active living becomes impossible. This kind of life portrays a probabilistic metapopulation-type (Fronhofer et al. 2012) life-history strategy as a combination of efficient reproduction, strong-enough dispersal of actively living cells, and a satisfactory abundance of suitable free niches at any given moment in time that the organism can potentially reach and inhabit.

An extreme case of the opposite type could be presented by an organism that has demonstrably lived, subsequently entered survival state, and then appears to remain there indefinitely thereby approaching the borderline of even being a living system anymore. A real life counterpart could be a bacterial spore or a dry seed of a flowering plant, both being what may be called individuals (of which the latter is a multicellular entity). If these structures do not exhibit any sign of active life, are they then alive or dead, living or inanimate at the time of observation?

Ultimately the “aliveness” of the organism in a situation like this cannot be determined unless we try to germinate the seed or spore. Depending on the species these kinds of structures can be extremely stable and inert, but not all of them will germinate. Not knowing beforehand what the outcome of the germination attempt would be for any one unit structure (success or failure) we may have to consider that in its survival form proper it is both alive and dead at the same time, in which case this survival stage in the system’s life presents a quantum state to the conceptual systems formalism of living system dynamics.

Interestingly, the existence of formal possibility for extremely stable survival-state occupancy makes it look like almost any kind of structural entity could be in this state and examined in the light of this living systems formalism. This could raise the issue of whether the proposed model outline is even too general, but the answer is no. It is correct that the survival state given, this model of living systems may also accommodate structurally organized states of inanimate matter. *Therefore*, being a living system comes down to the properties of the structural constitution of the individual living entity in question, its formal information storage properties, and the specific information that it contains. These features together specify the extent to which a structural organization can exhibit live behavior as determined by the biphasic reproduction-survival state transition framework.

All this results in an extended formal view of life as a system that on one side is conceptually determined purely by the survival function where it is conceptually allowed to apply also to inanimate organizations. On the ultimately opposite end of life resides pure and utter self-replication of the information-containing structure in question. This functional end provides a positive feedback loop for multiplicative existence of structural information-containing entities and possibly for their sustainable existence, formally for any kind of organization that can perform this function at a rate that is higher than the dissociation rate of the structures produced.

Not all information-containing structure in all environments have properties that enable them to live. But some clearly do, the biological organism being a prototypic example. A usual assumption in biological research is that organisms evolve to maximize reproduction. But in this model this evolutionary tendency is inherently embedded in the model formalism: There will simply be more cells that evolve towards maximizing reproductive active state living, than cells that spend excessive time in their survival state.

## Evolution In-between Reproduction and Survival

The ability to undergo adaptive evolution is a defining feature of biological organisms. Starting from the minimal-model case, the formal reproduction-survival state-transition framework may adapt and evolve to its environment in many different ways, just like a cell can undergo Darwinian adaptive phenotypic evolution with mutation and selection.

Adaptive periodic entry into survival state in a predictable fluctuating environment provides a mechanism for continuous long-term evolution towards more efficient active state living. When a cell returns from the survival state after a period of stress that would have otherwise killed it, it can continue its evolution recursively from the adaptational state where the previous round of active evolutionary living and reproduction had taken it. Sporadic entries into survival state are less likely to be equally effective in this sense, because they may take a cell into survival state also when it could alternatively undergo active state living. However, they can provide a probabilistic back-up system for organism’s survival in the case of stochastic catastrophic events that can take an actively living cell completely by surprise.

In the simplest possible minimal model scenario the survival transition may be direct and discrete, but in reality it seldom is. It appears that the cells of most real organisms spend most of their time in states where they invest simultaneously and in varying ratios to both reproduction ability and survival probability. In the system formalism they occupy *intermediate metastable transition states* that reside formally in-between the ultimately theoretical system-defining end-point states of maximum reproduction and absolute survival (see Figure 2). Because the overall evolution of a reproduction-survival state-transition system is towards active-state living, these intermediate states are likely to emerge into survival transition biology in the course of evolution as opposed to more immediate system progression in the direction of entering survival state.

Figure 2. A simple description of intermediate metastable survival transition states (m-states) that position along the linear continuum of survival transition progression in the formal state-space of survival transition biology.

Unicellular organisms with complex life cycles can be considered from this same survival transition point of view. For example, when the yeast *Schizosaccharomyces cerevisiae* leaves the active state in order to form spores, it must proceed through several identifiable stages that provide structure to its survival transition biology. The life cycle of the unicellular malaria-causing parasite *Plasmodium falciparum* is very complex and in many respects entirely different from the yeast life cycle, but it too can be viewed from the point of view of survival transition biology. It can be seen as a stage-wise realization of a balancing act between cellular reproduction and survival functions. Flexible cell-type differentiation processes take the system from one stage to the other as this organism of reproducing cells migrates through different tissue types in its two host organisms: the mosquito and the human.

In colonial multicellularity, presented for example by some aquatic green algae, single-cell individuals form multicellular entities but each cell retains its individualistic identity and potential for future reproduction. This kind of investment to cellular properties that enable multiple cells to organize into a single functional structure can physically aid the survival of them all. Functions that allow this behavior are not directly related to the reproduction operations of a single cell, but on system level they may still contribute to this aim – especially if conditions are not ideal for single-cell living when the colony forms and the cells in question are likely to be eventually forced to enter survival state.

Figure 3. An arbitrary example of an evolved survival transition framework topology with metastable transition states  $m_1$  and  $m_2$ . After leaving the active state the cells of this organism may still return directly from the  $m_1$ -state. Later each cell proceeds with the transition, either directly or via another intermediate state  $m_2$  that might only be available for the cells of a supporting cell line that further protect those cells of the organism that transit directly from  $m_1$  to survival state.

### Multicellular Organisms

On one hand, complex unicellular life cycles can be formally considered to be patterns in the state-transition formalism. On

the other hand, the different cell lineages of complex multicellular organisms can each be interpreted in the same way from the same state-transition perspective regarding *both* the evolution *and* the actual developmental progression of their cellular differentiation processes.

For example, rapidly proliferating cells of an early human embryo differentiate progressively as the organism matures, their reproduction diminishes. The cells acquire features that contribute to the integrity of the developmentally complex multicellular human entity, through cell-type specific functional and structural differentiation. They adopt a role as part of a multicell-complex (a human individual) as intermediate metastable survival transition cells, and instead of entering survival state they get to live in terms of their own higher-level organizational entity in places and environments where they could never live as solitary single-cell individuals. Uncontrolled reproduction is no longer the sought-for state for the primary existence of this organism's cells, as demonstrated by cancerous cells (Merlo et. al. 2006).

Multicellular individuals are considered to be organizational entities of lower-level unit-structures. As individuals, they become subject to the same system principles of reproduction-survival state-transition dynamics as are the cells on the lower level of organization. This adds a dimension to the overall complexity of the individual organism in question. The next level of complexity expectedly arises when the multicellular individuals form social groups. A starting point for addressing this kind of conceptual *living complexity* as a formal problem in the study of complex adaptive systems in general, is to propose that the more layers of living organization there are in the formal description of an individual organism, the more complex and multilayered the interaction patterns within and between reproduction-survival state-transition dynamics on all levels of its organization.

### Conclusion

A general scientific model of life must present it as something that can be established in the realm of chemistry, obeying the laws of physics, and being manifested in the form and function of all kinds of biological organisms. The proposed modeling approach enables introduction of general systems formalism for the description and definition of very different kinds of biological systems from a common systems point of view. It should be possible to take the formal system framework of the hereby proposed model and examine it together with the key attributes of life that were listed at the beginning of this article, to see how they can best fit together and thereby deliver a concise picture of living systems in general.

In the light of this conceptual framework, *living* may refer to the things that happen in terms of this framework. *Life* on the other hand is the entire identifiable emergent overall phenomenon that arises from the operation of the living systems. More specifically, the existence of life on Earth may be seen as patterns in space-time that emerge from the structure-based functioning of a subset of information-containing systems. Based on their organizational information-containing properties, they undergo operations in their prevailing environment that *channel available energy*

(Morowitz and Smith 2007) and matter into the processes of self-maintenance and self-reproduction.

The structure of the hereby-presented reproduction-survival systems model stems from what is generally known about simple living of biological organisms. Attributes of the model are very generic suggesting, that it will be possible to use it also for testing whether other kinds of system possess the kind of formal system properties that are needed, in order to have potential for reproduction-survival dynamics and adaptive evolutionary living.

Much work is to be done in order to examine the full potential of the proposed modeling formalism and the rules by which the proposed system dynamics can operate and evolve. But the ease, by which many different versions of natural life can simply be immediately positioned even to this rough prototypic model schematic, makes this approach seem very promising. Gaining a simple and useful general formalism for the definition, description and study of living and life-like system across disciplines would be a great improvement to the current situation.

## Acknowledgements

I would like to thank Jörkki J. Hyvönen and Michael Patra for important conversations regarding the main idea of this work. I also thank Kimmo Kaski for useful discussions and for providing the necessary facilities to carry out this research.

## Abstract

This paper addresses the problem of autonomous behaviors of virtual characters. We postulate that a behavior is regarded as autonomous when the actions performed by the agent result from the interaction between its internal dynamics and the environment, rather than being externally controlled. In this work, we argue that an autonomous behavior is an agent's solution to a given problem, which is obtained through a process of self-organization of the dynamics of a system that is composed of the agent's controller, its body and the environment. That process allows the emergence of complex behaviors without any description of actions or objectives. We show a technique capable of adapting an artificial neural network to consistently control virtual Khepera-like robots by means of simulated reproduction, with no measure of the robots' fitness. All the robots are either male or female, and they are capable of evolving different kinds of behaviors according to their own characteristics, guided solely by the environment's dynamics.

## Introduction

### Contextualization

In this paper, we address the problem of autonomous behaviors of virtual characters (Shao and Terzopoulos (2007); Whiting et al. (2010)). A behavior is considered *autonomous* when the actions performed by the agent result from a close interaction between its internal dynamics and the circumstantial events in the environment, rather than from external control or specification dictated by a pre-defined plan.

That definition of autonomous behavior seems to entail an apparent contradiction to the process of creating virtual characters. Given that true autonomy implies no predefined behaviors, how is it possible to *design* the internal dynamics of an agent that is supposed to interact autonomously with its environment? The attempt to answer that question led us to investigate ways of obtaining behaviors by emergence.

Emergence can be described as the appearance of a system's global characteristic that cannot be found in any of its parts (Klaus and Mainzer (2009)). For example, although a portion of water at normal temperature is in the liquid state, we cannot say that a single water molecule can display

this property. In general, the emergent properties are associated with dynamical patterns that get established through the interactions among the component parts of the system. In our particular case, the system should be considered as composed of the agent itself, defined by a virtual body and a controller, together with every aspect of the environment, both the objects and the lawful regularities that hold in the virtual world. In this setting, we define the notion of *emergent behavior* as follows: the behavior of a virtual character is called emergent when it is not explicitly described in any of the components of the system, and arises as a result of the dynamical interaction of the components, and their specific individual properties.

It is useful to think of the emergent behavior as an agent's solution to a given problem, which is obtained through a process of *self-organization*. Indeed, the real world's biological agents constantly come up with new behaviors to overcome challenges and to adapt to a changing environment. The emergence of a new behavior reflects the process of reorganization of the internal structures of the agent. In nature, this self-organization process is controlled mainly by Darwinian evolution dynamics: generation of diversity and natural selection.

These ideas have inspired many researchers to attempt to evolve neural controllers for virtual characters using Genetic Algorithms (GA) (Sims (1994); Nogueira et al. (2008); Pilat and Jacob (2010); Palmer and Chou (2012)). So, instead of anticipating and modelling all the ways in which the agent could possibly behave, the idea is to describe a task to be achieved (that is, to create a virtual environment with challenges for survival), and let the evolutionary process shape the virtual agent's control dynamics. That is expected to lead to the emergence of behaviors, which not only solve the task, but also are coherent with the capabilities of the agent's body and with the environment's characteristics.

We argue, however, that that approach leads only to a weak form of autonomy, because the GA guides the self-organization process using a *predefined* objective function. So, in that sense, behavior is still externally described. In nature, the quality or fitness of an agent depends on its in-

ternal constitution and the way it couples with the environment. Hence, the (natural) selection criteria also constitute an emergent characteristic of the system. In this work, in order to achieve a higher level of autonomy, we present a technique for obtaining emergent autonomous behaviors of virtual characters without an externally specified objective.

### Proposed Solution

In this paper, we study the emergence of autonomous behaviors of virtual Khepera-like robots with:

- Non-interpreted simplified “vision” sensors;
- Controller consisting of an Artificial Neural Network (ANN);
- Adaptation through simulated sexual reproduction.

We show that our technique is capable of generating multiple behaviors in a population of robots: foraging, mating and obstacle avoidance. In our experiments, we could also observe different behaviors according to the gender of the robot and a complex use of the sensors for navigation.

In “Related Works” Section, we discuss the attempts of the community in obtaining autonomous behaviors of artificial agents. One notice a research trend that seeks to reduce the amount of external information provided to the system, moving from the traditional objective-driven GA to a completely environment-driven evolution, using ideas based on reproduction dynamics, similar to our work.

In “Controller” Section we describe the controller used in our virtual robots and the genetic encoding we developed to evolve it, since our simulated reproduction technique is based on the exchange of genetic material between a pair of robots of opposite genders. In “The Experiment” Section, we report the experiments, explaining the constitution of the robots and of the environment, and analyzing the dynamics of the whole system. The obtained results presented in “Behaviors” Section and final discussions are made in conclusion.

### Related Works

Evolutionary computation has long been used as a tool to develop autonomous behaviors in artificial agents (Sims (1994); Palmer and Chou (2012)). Most works address behavior as a domain specific problem, and, traditionally, have proposed solutions, which, *a priori*, fix the objectives the agents need to achieve and the metric to evaluate how well the agents perform the task of meeting the objectives. However, there are also efforts along the line of creating techniques that incorporate additional aspects of natural selection in order to obtain greater complexity and autonomy of behaviors. In this section, we will briefly discuss the research path from the explicitly objective-driven canonical genetic algorithm to environment-driven open-ended evolution (Bredeche and Montanier (2012)).

### Objective-driven evolution

The Virtual Reality community has extensively applied GAs in order to create virtual worlds automatically, in which autonomous characters present convincing behaviors. The proposed techniques are usually problem-oriented, with the evolutionary processes guided by fitness functions designed according to the expected behaviors of the characters. Some examples are the distance-based fitness of the walkers from Sims (1994) and Nogueira et al. (2008), or the speed-based fitness of the light followers from Pilat and Jacob (2010). Palmer and Chou (2012) went one step further by proposing a distributed GA that coevolves an interacting population of virtual hunter robots, instead of evolving a single individual at a time without taking into account possible interactions among them. However, the agents reproduce according to their relative fitness, based on a harvest score. The main characteristic of these works is the generation of behaviors that solve the problem in a way that is implicitly designed in the objective function.

Indeed, addressing the problem of autonomous behaviors through a problem-oriented technique, such as the canonical GA, leads to the evolution of agents capable of solving a single problem at a time. In order to achieve behavioral diversity, Schrum and Miikkulainen (2010) studied fitness-based shaping of behaviors to multiobjective domains, by dividing problems into a set of goals, i.e., a group of multiple fitness measures. A battle domain involving a scripted virtual fighter and a group of virtual monsters is used to illustrate the technique. The monsters had to maximize the inflicted damage, to minimize the received damage, and to maximize their life span. Another study that focuses on behavioral diversity is presented by Lehman and Stanley (2011), and suggests that one should abandon specific objectives and guide the search towards the novelty of solutions. These works attempt to overcome GA’s lack of behavioral diversity by proposing ways of evolving several objectives simultaneously. However, each problem an agent should solve has to be properly predefined, because it is selected through some type of performance measure.

The effects of sexual gender discrimination were also investigated through evolutionary computation. Zhang et al. (2009) proposed a GA that uses a population consisting of male and female individuals, and a fitness function based on a model of the Baldwin effect. The work is concerned with the sexual reproduction in GA, and presents numerical simulation benchmarks in order to show improvements regarding convergence speeds, prevention of premature convergence and ability to solving high dimension problems. That work incorporates another feature of natural selection to GA: the gender differentiation. However, it does not specifically analyze the effects of this new feature on the generated behavior.

Da Rold et al. (2011) studied the effects of gender determination on behavior through a simulation with male and female robots in a virtual world containing energy resources.

The reported results show that the robots acquired different patterns of behaviors according to the gender and to the pregnancy status of the females. However, the sexual dynamics was not incorporated into the evolutionary algorithm itself, since a simple GA was used, with a fitness function based on the number of matings. Mating consists in a contact between two robots of opposite genders in which the female robot gets a psychological pregnancy (i.e., it does not generate offspring), remaining in that state for a specific amount of time, during which it cannot take part in another mating. For the GA, each gender constitutes a different population, which are evolved separately, although the evaluation of the individuals depends on the interaction between the two types of robots. The exhibited behavioral diversity is related to the fact that agents with different characteristics have to solve the same problem in different ways, suggesting that gender determination is an important aspect of natural selection. However, the way this feature is exploited in that work still shows the convergence of solutions to a predefined problem.

All the works discussed so far have the common characteristic of a centralized evaluation of the agents' fitness. A paradigm shift is presented in Embodied Evolution (Watson et al. (2002)), a distributed evolutionary algorithm embodied in physical robots. In that work, the agents have a reproduction function explicitly defined in terms of their energy level, in such a way that the genes that control robots with higher energy levels have greater probability of spreading out, while those that control robots with lower energy levels have greater probability of being replaced. The environment is endowed with energy resources, and the robots that are capable of benefiting the most from them are the ones that will spread their genes. Notice that, although the robots develop a behavior that is not directly selected, one can still say that the probability associated with the reproduction function plays the role of a fitness function, because it is explicitly designed to select individuals according to the preconception that those with higher levels of energy are the fittest ones.

### Environment-driven evolution

In the environment-driven evolution approach, no fitness function is described, and the evolution is carried out by environmental pressures. That is, there is no explicit evaluation of an individual in order to select it or not, but the better performing individuals will naturally spread out according to the dynamics of the whole system.

Bredecche et al. (Bredecche and Montanier (2010); Bredecche et al. (2012)) applied this idea to evolve a population of autonomous real robots. They developed the Environment-driven Distributed Evolutionary Adaptation algorithm (EDEA), and showed that their algorithm is robust to the so called reality gap: a swarm of real robots is able to evolve efficient survival behavior strategies, with no

fitness function being ever formulated. Although their work is presented mainly from an engineering point of view, many interesting conceptual discussions arise in this context, most of them independent of particular implementations.

The authors observe that the key to EDEA is the implicit nature of fitness function, that may be seen as a result of two motivations (Bredecche and Montanier (2010)):

- **extrinsic motivation:** *agent must cope with environmental constraints in order to maximize survival, which results solely from the interaction between the agent and the environment around (...);*
- **intrinsic motivation:** *set of parameters (ie. "genome") must spread across the population to survive, which is imposed by the algorithmic nature of the evolutionary process. Therefore, genomes are naturally biased towards producing efficient mating behaviors (...).*

A low correlation between the two motivations can increase the problem's complexity, since it will possibly imply conflicting objectives. Thus, an efficient environment-driven algorithm must address a "trade-off between extrinsic and intrinsic motivations as the optimal genome should reach the point of equilibrium where genome spread is maximum (e.g. looking for mating opportunities) with regards to survival efficiency (e.g. ensuring energetic autonomy)" (Bredecche and Montanier (2010)).

The idea of environment-driven evolution fits well with our analysis of emergent autonomous behavior, since both claim that the evolution of the system should be guided by the dynamics of the interactions among its component parts. In this sense, to be precise, we can say that the evolution is not only environmentally driven, but also population-driven, or better, system-wise driven. We note that every aspect of the system may offer an opportunity for improving adaptation, in ways that cannot be foreseen *a priori*. Individual characteristics of the agents and specific behaviors cannot be judged 'good' or 'bad' in isolation, but depend on the behavior of the rest of the population, and on the current dynamics of the system. The experiment in Bredecche et al. (2012) illustrates this point well, where one can see that the individual behavior of going towards the 'sun' is 'good' (i.e., favors reproduction) because a large number of robots in the population also tend to do so. From this perspective, we can say that there is not even an implicit fixed fitness function, since the dynamics of the system may change, and so the conditions for adaptation also may change. In other words, the implicit fitness function may be considered as another emergent aspect of the system.

In this paper, we study the emergence of autonomous behavior of virtual agents, using environment-driven evolution. Simulations gave us greater flexibility and allowed us to implement robotic sexual reproduction, a feature that is still impractical to obtain in real world experiments. Therefore, we could explore additional aspects of the emergence

of autonomous behaviors, investigating, for example, the effects of population size and resources fluctuation on competitive behavior, the system's ability to follow alternative evolutionary paths, and the impact of gender differentiation on the generation of behavioral diversity.

## The Controller

### The Neural Network

The controller is essentially a Continuous Time Recurrent Neural Network (CTRNN), whose neurons are modeled in the following general form:

$$\frac{dy_i}{dt} = \frac{1}{\tau_i}(-y_i + \sum_{j=1}^n w_{ji}f(s_j) + I) \quad (1)$$

where  $t$  is time,  $y_i$  and  $\tau_i$  are, respectively, the internal state and the time constant for each neuron  $i$ ,  $w_{ji}$  is the weight of the  $j$ th input synapse of neuron  $i$ ,  $s_j$  is the state of the neuron linked to the  $j$ th input synapse,  $f()$  is the activation function of a neuron and  $I$  represents a constant input to neurons.

Furthermore, we also use two types of neurons that do not have internal dynamics: the afferent and the efferent neurons. An afferent neuron, whose internal state is the value of one of the network's input, cannot receive input from another neuron. The afferent neurons constitute the network's input layer. An efferent neuron, on the other hand, is part of the network's output layer, and its internal state is the average of the internal states of all the neurons connected to it.

### The Genetic Encoding

The controller of each robot is encoded into two chromosomes. The first chromosome encodes the stimulus  $I$  (Equation 1), and the second, which we call the Network Chromosome (NC), holds the gender of the robot and the description of the ANN itself. This grouping was chosen so that a "male brain" could evolve together with a "male gene", and a "female brain" could do so with a "female gene", while the same constant  $I$  could be tested with different networks.

The NC is defined according to a simplified version of Mattiussi's Analog Genetic Encoding (AGE) (Mattiussi and Floreano (2007)) focused at evolving a CTRNN for the control of virtual characters. To create the synapses, AGE defines an alignment score: a network-specific interaction map that leads to a complex chromosomal representation. Our proposal keeps the idea of an implicit interaction between genes that encode the synapses. However, we specify a simpler similarity function, which not only makes it possible to describe the chromosome as a simple binary array, that encodes the parameters of the network in a more straightforward way, but also maintains the advantageous properties of AGE's interaction maps for ANNs evolution.

In implicit interaction, while the neurons are explicitly described in the chromosome, the synapses are implicitly

defined, since they are formed by the interaction between genes, and not by a gene itself. To decode the ANN, we basically follow a two-step process:

1. Read the chromosome and extract the neurons and their respective input and output "ports", which we call "Neuronic Terminals" (TR);
2. Create the synapses from the interaction between the TRs.

This encoding scheme allows us to easily search augmenting topologies of neural networks.

In our work, a chromosome is an array of bits in which a single bit defines a "gender gene", and each group of 32 bits afterwards defines a regular gene. The single bit "gender gene" was introduced in order to enable sexual reproduction. The other genes are defined by a tuple  $\langle id, v \rangle$ , where  $id$  identifies the encoded element, i.e., whether it is a neuron or a TR, and  $v$  is a value that indicates a property of the encoded element.

To decode the NC, we read the first bit to determine the gender of the robot, and then we read each subsequent gene (group of 32 bits) isolating its identifier from its value. A gene identified as a neuron creates a neuron element in the network. In the decoding sequence, any TR gene that appears before the first neuron gene is ignored; and after each new neuron gene, only the first two TR genes are considered. The first of those valid TR genes determines its input terminal, while the second TR determines its output terminal. The value of a neuron specifies its time constant  $\tau_i$  (Equation 1), and the values of the TRs are used to calculate the synapses' weights between the neurons.

The first eight bits of the gene hold the  $id$  and are decoded according to Table 1. Note that the probability  $P(TR)$  is greater than  $P(N)$ , since we expect more synapses than neurons.

Id value	Meaning
$0 \leq id \leq 51$	Neuron (N)
$52 \leq id \leq 255$	Neuronic Terminal (TR)

The last 24 bits of the gene encode the value  $v$ , which is linearly mapped into a floating-point number in the range  $[-1, 1]$ . If the value is related to a neuron gene, the result is directly attributed to the time constant of the neuron. If related to a TR, it is further used to calculate a synapse weight according to the equation:

$$w(i, o) = \frac{eb \cdot (i + o)}{nb \cdot 2}, \quad (2)$$

where  $w$  is the weight of a synapse that links an output terminal of value  $o$  with an input terminal of value  $i$ . The symbol  $nb$  indicates the total number of bits that represent the value

(24 bits), and  $eb$  is the number of equal bits at the same position between the binary representations of  $i$  and  $o$ . We also defined an existence condition empirically to increase topological diversity: if  $\lfloor eb/4 \rfloor \bmod 3 = 0$  then  $w(i, o) = 0$ . The whole process of network decoding is shown in Figure 1.

Figure 1: Building the network: First we decode the neurons and their respective terminals, then we apply Equation 2 to each pair of terminals to create the synapses. Only one synapse was created due to the existence condition (see text).

Regarding the input and output neurons, suppose that the robot has  $s$  sensors and  $m$  motors. In order to keep some structure of the ANN in the chromosome, we fix the first  $s$  genes that encode neurons to be afferent neurons, while we set the last  $m$  genes that encode neurons to be efferent neurons, that is, the inputs of the network are described in the beginning of the chromosome, the internal neurons are defined in the middle of the chromosome and the outputs are placed in the final part of the chromosome.

## The Experiment

### System description

Our simulation was developed with the *Irrlicht 3D Engine*<sup>1</sup>, with physics provided by the *Bullet Physics Engine*<sup>2</sup>. The environment is populated by simulated “male” and “female” robots that live in a square room, bounded by walls, and filled with randomly distributed fruits (Figure 2), from which the robots can get energy to live.

The robots have cylindrical bodies. A black box in the cylindrical surface represents, at the same time, the eye, the mouth and the genitals of the robot and determines its front part. The robots guide themselves through the environment using their vision, obtain energy by eating fruits and reproduce through mating. Each of these functions are better described next.

The robot’s vision is determined by three sensors positioned in the black box (the eye), as shown in Figure 3. Each sensor is able to catch the normalized distance ( $[0, 1]$ ) to the nearest object inside its “Field Of Sense” (FOS) with respect

Figure 2: The environment.

to its reach (the maximum detection distance of a sensor). The sensor that is located at the center of the eye is specialized to detect walls only, and has a FOS of  $120^\circ$  and a reach of approximately  $4 * r$ , where  $r$  is the radius of the robot’s body. The other two sensors, placed at each side of the eye, are able to sense male robots, female robots and fruits, and have a FOS of  $10^\circ$  and reach of approximately  $14 * r$ . Those values were empirically chosen.

The wall sensor generates only one floating-point value indicating the normalized distance to the wall. In addition to the distance value, each one of the other two sensors also generate three bits that indicate the type of object sensed, i.e., a male robot, a female robot or a fruit. That means that the whole vision apparatus generates nine values.

Figure 3: The distribution of the three vision sensors. The dotted lines represent the FOS of the wall sensor. The dashed lines and the dashed-dotted lines represent, respectively, the left sensor and the right sensor of robots/fruits.

Furthermore, there are proprioceptive senses of fertility and energy. The sense of fertility enables a male robot to know when it is infertile (1 if infertile, 0 otherwise) and a female robot to know when it is pregnant (1 if pregnant, 0 otherwise). The sense of energy enables a robot to know its level of energy, which ranges from 0 (the robot is fully energized) to 1 (the robot is totally exhausted). Therefore, the strength of the signal allows the robot to perceive when its energy is finishing. Thus, there are nine signals of vision and two signals of proprioceptive senses, leading to an ANN with eleven afferent neurons.

A robot has two motors, which are controlled by two efferent neurons respectively. When the first motor receives a signal from its efferent neuron, it moves the robot forward in case the value of the signal is positive, and moves the robot

<sup>1</sup><http://irrlicht.sourceforge.net/>

<sup>2</sup><http://bulletphysics.org/>

backward if the signal is negative. Likewise, the other motor makes the robot turn right in the event of a positive signal, and makes the robot turn left if the received signal is negative. The actions of the motors are simplified and are not physically accurate. The amplitude of the signals generated by the efferent neurons are increased 100 times, before they are applied as the robot's speed.

The energy level of a robot increases 7,500 energy units (eu) whenever a fruit is eaten, i.e., when the robot touches a fruit with its mouth. The maximum energy value is 100,000eu and continuously decreases in direct proportion to the applied motor signals plus a value proportional to the robot's age. If the energy is exhausted, the robot dies and is removed from the environment. Thus, for example, suppose that  $o_1$  and  $o_2$  are the amplified output of the two efferent neurons of the ANN and that  $t$  is the robot's age. Then, the energy consumption  $C$  is calculated according to the equation:

$$C = (|o_1| + |o_2|)^2 + \frac{t}{75.0}. \quad (3)$$

Regarding the dynamics of fruits replacement, at each time step, a new fruit is randomly placed in the room, provided that:

- The number of fruits does not exceed 30 fruits; and
- The total number of objects, i.e., the number of fruits plus the number of robots, does not exceed the limit of 45 objects.

### Simulated Reproduction

The simulation starts with 15 robots. If the population becomes smaller than 6 individuals, we place 15 new random individuals in random positions. Each of these robots has its energy randomly initialized with a value between 10,000eu and 20,000eu. The genetic information is also randomly generated. Since we have just one bit to express the robot's gender, 50% of the population consists of female robots.

Mating is consummated whenever a male robot's genitals (the black box) touch the body (any part of the cylinder) of a fertile female robot. A female is fertile if its energy is greater than 25,000eu. Since any robot has an initial energy of 20,000eu at most, every female is infertile at first, and needs to eat some fruits in order to reproduce.

If mating occurs, the male robot gets infertile during 250 simulation steps and the female robot gets pregnant. The new robot is placed adjacent to its mother, so the female robots remains pregnant until she goes to a free place where its child can be positioned. The child's energy is initialized with a value between 15,000eu and 25,000eu, which is taken from its mother. Therefore, when, at the moment it gets pregnant, a female robot has low energy (a value close to 25,000eu), there is a higher probability that it will die sooner. After giving birth, the female gets infertile during 250 simulation steps to avoid a pregnancy right after the other.

The chromosomes of the new individual are generated by crossing over the parents' chromosomes. Since a chromosome is simply an array of bits, the process of crossover sets two breakpoints randomly, and exchange the bits between the pair of chromosomes at the defined range. Note that this method can generate mutation by breaking a gene, since it is defined by a group of 32 bits. This is expected to create variability. We also apply an explicit mutation, randomly changing bits in the chromosomes with a probability of 0.1%. Since after the crossover we still have a pair of chromosomes, we simply discard one randomly.

The genetic information of an individual encodes its ANN directly. Therefore, when crossover takes place between a pair of chromosomes of different individuals, the process can be viewed as if pieces of each individual's brains were being exchanged. Consequently, the newly generated brain can lead to a robot with behavioral traits inherited from both parents.

### Life Dynamics

Note that, according to the reproduction dynamics described, if there is a high density of fruits and robots at the environment, mating is relatively easy to occur and can occasionally happen in a random way. In fact, this is necessary to avoid endless resumptions of the population and to bring some line of evolution. In so far as that the population evolves, those individuals who present some type of strategy are at a greater advantage and will impose new conditions to the system, causing random behaviors to decrease.

Another important point to comment is the balance between the number of individuals in the population and the amount of energy resources. According to the fruits' replacement dynamics, if the population grows, the number of fruits available reduces. Therefore, with scarce energy resources in the environment, the robots with worse performance will die. Note that, if the population size grows above 45, no fruit will appear and, thus, the robots that are less efficient will die before new fruits appear. That dynamics prevents population explosion automatically and provides some selective pressure, which guides evolution.

### Behaviors

We ran the simulation several times and obtained mixed interesting behaviors. Due to space constraints, we cannot present the results of all the runs<sup>3</sup>. Therefore, we will focus the discussion in a common recurring result: females tend to seek food and males tend to look for mating. Furthermore, the robots learned how to deviate from the wall and how to use their simple vision to guide themselves through the environment efficiently and meet their needs. In Figure 4, a sequence of frames shows two robots presenting the mentioned behaviors, which are detailed in the respective labels.

<sup>3</sup>Watch the video with multiple runs of our experiments: <https://www.youtube.com/watch?v=zyDdjD6d5CE>

Other interesting strategies also emerged from the population in different simulation runs, always leading to the population's survival and stability.

Figure 4: Commonly observed behaviors. Note that the male robot (the one with the arrow indicating his direction) follows the female robot that seeks the fruit. Another interesting point to emphasize, is the complex use of the simple vision: the female senses the fruit with her left sensor (Frame 1), and then turns left (Frames 2 and 3) in order to use the right sensor to determine the direction to follow, correcting the movements and maintaining the object between the two sensors (Frames 4 and 5). Frames 6, 7 and 8 show the female robot turning right in order to deviate from the wall after catching the fruit.

Since we do not have to define any objective, there is no variable to watch in order to follow convergence toward an expected behavior. However, some values indicate the evolution of the whole population, and the analysis of the relations among those values allows us to objectively demonstrate the emergence of the described behaviors.

The mean lifespan of the population over a period of time is a good parameter to see the emergence of some strategy of the population in order to survive. Another aspect that can indicate characteristics of the behaviors is the correlation between the male and female lifespans. Figure 5 shows the mean lifespans of the population in the simulation run described in Figure 4. Note that the female robots have converged to a mean lifespan greater than that of male robots. This is related to the fact that the female robots were always searching for food actively, while the male robots caught a fruit occasionally. However, both gender increased their efficiencies.

The average number of collected fruits and the average number of matings are good parameters to analyze the behavioral characteristics of each gender. In Figure 6a we can see that, in the analyzed simulation run, the female robots converged to collect about 10 fruit on average during their lifespan, while the average number of fruits collected by the male robots is less than one, demonstrating the preference of female robots for collecting fruits. In Figure 6b, we can note the preference of the male robots for the mating behavior. However, it is important to mention that other runs presented different strategies, such as, for example, the for-

Figure 5: Mean lifespan of the population every 900 seconds of simulation.

mation of clusters of robots, which increase the probability of matings, and the presence of robots with both foraging and mating behaviors, regardless of the gender.

The observation of the population size at a given time along with the average number of collected fruits and the mean lifespan, shows some aspects of the general behavior of the whole population. Note that there is a peak in the graph of Figure 6a before convergence around a certain smaller value. Analyzing Figures 5 and 6a at approximately the same time (about 4000 seconds and 1 hour, respectively), we can see that as the robots learn how to catch fruits, there is an increase in the mean lifespan. As described, the number of fruits placed in the environment depends on the number of robots. So, an increase in the mean lifespan leads to population growth and, consequently, to reduction of the available resources, hence reducing the average number of collected fruits per robot. That leads to a balance of the population size, preventing population explosion, as shown in Figure 7.

Figure 6: Average number of collected fruits and matings every 900 seconds of simulation. (a) The greater number of fruits collected by the female robots indicates their behavioral tendency to foraging. (b) Note the increase of matings with time. This shows a male preference to such behavior.

## Conclusions

We described an artificial life system where virtual Khepera-like robots developed multiple autonomous behaviors, without any description of their objectives. The observed behaviors emerged solely from the self-organization of the dynam-

Figure 7: Population size every 30 minutes. Note that with 2.5 hours of simulation, the population size increases to about 45 individuals and then is balanced around this number due to shortage of resources caused by the large amount of robots that developed the foraging behavior.

ics of the system. The robots were divided into genders and were controlled by an ANN. We presented a genetic encoding for the ANN, which allowed the adaptation of controllers through simulated reproduction, providing an implementation of environment-driven evolution.

The system was capable of exhibiting several types of behaviors, according to the robots' characteristics. A common situation observed, was the emergence of mating behavior in male robots and foraging behavior in female robots. A single individual was also able to show multiple behaviors, such as avoiding collisions with the walls and use of vision to pursue its own objectives. Although different behaviors have emerged from different simulation runs, the system was always able to show the evolution of robots presenting strategies that led to an increase in the mean lifespan and in the size of the population.

The results of our experiments show that the self-organization of the system is capable of producing an intimate coupling between agent and environment, producing complex and natural behaviors without any *a priori* description. This characteristic is clearly illustrated with the strategy developed by the virtual agent to compensate for its primitive visual sensory apparatus and to be able to find a direction to an object, an information that is not originally provided by the sensors.

## Abstract

Most conventional robust design methods assume design solutions are fixed values. Using these methods, designers set each control factor to a fixed value to maximize the robustness of objective characteristics. However, fluctuations in the objective characteristic often exceed the allowable range in a design problem. Consequently, obtaining sufficient robustness is difficult using conventional methods.

This research defines adjustable control factors whose values can be adjusted within a given range to increase robustness and proposes a method to calculate robustness, including factors to adjust the objective characteristic and to derive optimum ranges of the factors. The robustness index, which indicates the feasibility that the objective characteristic values are within the tolerance by the adjustment, is calculated by the Monte Carlo method, while the range of adjustable control factors is optimized using the Vector evaluated particle swarm optimization. Finally, an engineering example is presented to demonstrate the applicability of the proposed method.

## Introduction

Robust design aims to ensure product performance robustness against fluctuant factors, such as user characteristics and material properties, by deriving the optimum (unique) value of the design parameter (design solution). Due to globalized markets and material procurement, robust design has received much attention, and many robust design methods have been proposed (Matsuoka 2010). Some methods evaluate robustness of the objective characteristic using an orthogonal array for efficiency (Sundaresan et al. 1991; Taguchi, 1993; Yu and Ishii, 1998ab), while others derive robustness using the objective characteristic values calculated via a Taylor series approximation (Arakawa and Yamakawa, 1995; Belegundu and Zhang, 1992; Emch and Parkinson 1994; Parkinson et al. 1993, 1995; Ramakrishnan and Rao, 1996; Zhu and Ting, 2001). Additionally robustness has been calculated as the feasibility of the objective characteristic being within the tolerance to consider the objective characteristic distribution (Eggert and Mayne, 1993; Watai et al. 2009).

In most conventional methods, designers set control factors to fixed values to maximize the robustness. In cases where the objective characteristic distribution is smaller than the tolerance (Figure 1a), these methods can derive a design solution (optimized control factor values)  $x_0$  with sufficient

robustness. However, in cases where the objective characteristic distribution is larger than the tolerance (Figure 1b), a solution to sufficiently maximize robustness cannot be obtained. In such cases, the control factors must be adjusted to ensure robustness. In other words, as the values of the control factors are varied, the whole of the objective characteristic distribution should be located within the tolerance (Figure 1c).

The concept of adjusting the factors originates from Taguchi's method (Taguchi, 1993). In this method, the control factors are set to minimize the objective characteristic fluctuation, and then the designer selects a tuning factor, which has a negligible effect on the fluctuation, to minimize the difference between the nominal value of the objective characteristic and its target value. Otto (Otto and Antonsson, 1993) assumed the tuning factor is adjusted after the fluctuation of objective characteristic. Hence, after the objective characteristic fluctuates, the factors are altered to minimize the difference between the fluctuated objective characteristic values and their target values. Otto proposed a method to evaluate the robustness using the expected value of the objective characteristic adjusted by the tuning factors. This method provided a new concept of robustness in which an adjustment improves the robustness and it helps relax the design requirements such as dimension tolerance and material property tolerance. However, Otto's method is not applicable to design problems where the designer chooses the tuning factors and their adjustable ranges because these parameters are preliminarily set in Otto's method. This is a common problem in mechanical design. For example, to design a seat, the designer must determine which adjustable mechanism, such as seat reclining mechanism, and its adjustable range to apply to the seat. Because a method to address such a design problem has yet to be proposed, the designer must determine these parameters using his/her personal design experience.

This research proposes a method to derive the optimum range for the adjustable factors which are chosen adequately to improve the robustness of the objective characteristics. This paper is divided as follows. Section 2 presents definitions and terminologies. The proposed robustness index, calculation method, and range optimization of the factors using the Vector evaluated particle swarm optimization (VEPSO) are described in Section 3. Section 4 illustrates an application of the proposed method to a seat design problem, while Section 5 provides conclusions and the future research direction.

Figure 1: Conceptual illustration of a design problem that includes an factor whose value is adjustable elements)

## Definitions and terminologies

In robust design, objective characteristic (product performance)  $y$  fluctuates according to fluctuant factors (control factors  $x$  and noise factors  $z$ ). Although the values of control factors fluctuate, designers can set their nominal values, but not those of noise factors. In this paper, adjustable control factors (hereinafter called ACFs) whose values  $t$  can be adjusted in the adjustable range  $[t_l, t_u]$  anytime while using or manufacturing the product to maintain the objective characteristic are newly defined.  $t_l$  and  $t_u$  are the lower and upper values of ACFs, respectively. ACFs are similar to the tuning factors defined in Otto's method (Otto and Antonsson, 1993) with respect to their adjustment, but the adjustable ranges of ACFs and tuning factors differ (i.e., the designer defines the ranges of the ACFs).

The concept of robustness in this research is defined below. If the tolerance of objective characteristic  $[y_l, y_u]$  exists as shown in Figure 1, then ACFs can be adjusted to locate each fluctuation value of the objective characteristic within the tolerance. Hence, the robustness index for ACFs ( $R_A$ ) is defined as the feasibility that the objective characteristic values are within the tolerance at least once, by the adjustment of ACFs. Using ACFs and  $R_A$ , design problems in this research are expressed as:

$$\begin{aligned} &\text{Find } [t_l, t_u], x \\ &\text{to maximize } R_A( y(= f(x, z, t)) ) \\ &\text{to minimize } |t_u - t_l| \end{aligned} \quad (1)$$

where  $f$  is the objective function. To prevent an unnecessary expansion of the ACF ranges, which increases the production costs and failure rate, this formulation does not only maximize  $R_A$ . Minimizing the size of the range described in Equation (1) is an example of preventing an unnecessary expansion because other factors (e.g., the form and location of the range) can lead to the aforementioned issues.

Below are definitions and descriptions of the terminologies used in this paper.

*Objective characteristic* ( $y = f(x, z, t)$ ): The characteristic to express the function of the design objective, and is calculated by objective function  $f$ .

*Control factors* ( $x = \{x_i\}, i=1, 2, \dots, n_x$ ): Factors whose nominal values are set by the designer, but fluctuate the objective characteristic.  $n_x$  represents the total number of control factors.

*Noise factors* ( $z = \{z_i\}, i=1, 2, \dots, n_z$ ): Factors that fluctuate the objective characteristic, but their nominal values cannot be set by designers.  $n_z$  expresses the total number of noise factors.

*ACFs* ( $t = \{t_i\}, i=1, 2, \dots, n_t$ ): Control factors with nominal values that can be adjusted within their adjustable ranges.  $n_t$  denotes the total number of ACFs.

*Adjustable range of ACFs* ( $[t_u, t_l]$ ): The range, determined by the designer, where the ACFs are adjustable.

*Assignable points of ACFs* ( $\{t_j\}, j=1, 2, \dots, n_{ap}$ ): The combinations of ACFs' values that can be varied to be within the adjustable range.  $n_{ap}$  denotes the number of ACFs' assignable points.

*Robustness index* ( $R_A$ ): Index to evaluate the robustness of the objective characteristics with regards to the ACFs adjustment.

## Robust design method for ACFs

### A robustness index for ACFs

In conventional robust design methods, robustness indices are approximated to improve the calculated efficiency. For example, the index in Ramakrishnan's method (Ramakrishnan and Rao, 1996), which is the weighted sum of the mean value and standard deviation of the objective characteristic, is calculated using a Taylor series approximation. However, approximated values significantly differ from the actual values or cannot be derived in the cases where the followings are not satisfied: (1) the objective characteristics monotonically increase or decrease with respect to the factors, (2) the objective function is differentiable, (3) the fluctuations in the factors are sufficiently small, and (4) the factors are independent from each other.

The proposed robustness index must be calculated accurately because the adjustable range must be minimized, as shown in

Equation (1). In other words, using an accurate robustness index, the designers must set the adjustable range as small as possible. Consequently, the Monte Carlo method, which derives accurate values but is time consuming, is applied to calculate the index. The calculation methods is described below.

All ACFs' assignable point values should be used to calculate  $R_A$ . Specifically, sets of objective characteristic fluctuations that satisfy the tolerance are derived with respect to all assignable point values  $t_j$ , as shown in Figure 2.  $R_A$  is calculated as the ratio of the sum of the sets of fluctuant combinations of  $x$  and  $z$  where at least one of the objective characteristic values  $y_j$  derived from  $t_j$  is within the tolerance as shown in Equation (2).

$$R_A = P \left[ \bigcup_{j=1}^n \{ C(x, z) | y_1 \leq f(x, z, t_j) \leq y_u \} \right], \quad (2)$$

where the square bracket expresses a set of  $C(x, z)$  where the objective characteristic is located within the tolerance by adjusting ACFs. This means  $R_A$  is the rate of the set and the entire set. The assignable point values are expressed as a finite number of discontinuous values  $t_j$  because  $R_A$  is calculated using the Monte Carlo method. The number of the assignable (discontinuous) values should be sufficient to assume the ACF is continuous. However, the number should be decreased if the calculation amount is too large. To calculate  $R_A$ , first,  $s$  random combinations of the control and noise factors are generated based on their probability density functions. Second, objective characteristic  $y_i$  is calculated using the generated random combinations  $\{x_i, z_i\}$  ( $i=1, 2, \dots, s$ ) and all the assignable point values. That is, the number of calculating objective characteristic values is the product of the random combination number  $s$  and the assignable points numbers of ACFs. Finally, the values calculated from each random combinations of  $x_i$  and  $z_i$  are assessed to determine whether at least one of the calculated values is within the tolerance (i.e., at least one assignable point which consists an objective characteristic value that satisfies the tolerance). Then  $R_A$  is calculated as:

$$R_A = \frac{1}{s} \sum_{i=1}^s M_i$$

$$\left( M_i = \begin{cases} 1 & (\exists t \in \{t_j\}; y_1 \leq f(x_i, z_i, t) \leq y_u) \\ 0 & (\text{otherwise}) \end{cases} \right) \quad (3)$$

$$j = 1, 2, \dots, n_{ap}$$

### Adjustable range optimization

This study proposed a optimization algorithm using the VEPSO in order to solve the design problem of Equation 1. An outline of the VEPSO and the algorithm using it are described below.

**Outline of VEPSO.** The VEPSO (Vlachogiannis and Lee, 2005, 2009) is an improved method of the PSO (Kennedy and Eberhart, 1995) that is one of the representative

Figure 2: Set of the objective characteristic fluctuations used to calculate the robustness index

metaheuristics, in order to handle the multi objective optimization problems. The PSO imitates the movement of organisms in a bird flock or fish school and searches a solution using the information both from the individuals (particles) and their swarm. The VEPSO assigns an objective to each of swarms and searches a solution using the information inside or between swarms. The location vector (i.e. design variables) of the  $i$  th particle in the  $j$  th swarm  $x_i^{[j]}$  is updated as follows:

$$x_i^{[j]}(T+1) = x_i^{[j]}(T) + v_i^{[j]}(T), \quad (4)$$

where,  $T$  is the number of iterations.  $v$  is the velocity vector to direct the particles to the updated locations and is calculated as:

$$v_i^{[j]}(T+1) = k [ w v_i^{[j]}(T) + c_1 r_1 \{ x_{pb,i}^{[j]}(T) - x_i^{[j]}(T) \} + c_2 r_2 \{ x_{gb,i}^{[s]}(T) - x_i^{[j]}(T) \} ]$$

$$\left( s = \begin{cases} M & \text{if } j = 1, \\ j-1 & \text{if } j = 2, 3, \dots, M \end{cases} \right), \quad (5)$$

where,  $M$  is the number of swarms;  $c_1$  and  $c_2$  are the parameters to express the degree of incidence of the private best location of each particle  $x_{pb}$  and the global best location  $x_{gb}$ , respectively;  $r_1$  and  $r_2$  denote the random numbers uniformly distributed in  $[0, 1]$ .  $w$  is the parameter to define the effect of the current velocity vector and decreases based on  $T$  as shown in the following equation:

$$w(T) = w_{\max} - \frac{w_{\max} - w_{\min}}{T_{\max}} \cdot T, \quad (6)$$

where,  $w_{\max}$  and  $w_{\min}$  are the maximum and minimum value of  $w$ .  $T_{\max}$  is the maximum number of the iterations.  $k$  denotes the parameter relating the convergence performance and expressed as follows:

$$k = \frac{2}{2 - \varphi - \sqrt{\varphi^2 - 4\varphi}} \quad (\varphi = c_1 + c_2). \quad (7)$$

As shown in Equation (5), the velocity vectors are defined using the global best locations of the different swarms. This enables the solution search based on the information from the other swarms and the global locations (solutions) of the swarms to approach each other. Therefore, the solution search

of the VEPSO has the following features: assigning a objective to each of swarms and searching the solutions located close to each other. These features generate the following merits to solve the robust design problem (Equation (1)): 1) the design solution (assignable points) to ensure the robustness can be efficiently derived by assigning the robustness regarding the part of the fluctuation of the factors to each of the swarm; 2) the distance between assignable points (the adjustable range) can be smaller.

**Procedure to derive optimum adjustable range using VEPSO.** This study amended the robustness index (Equation (2)) in order to evaluate each assignable point that assures the robustness regarding the part of the fluctuation of the factors. The robustness assured by the  $j$  th assignable point is expressed as follows:

$$R_j = P[C(x, z)_j | y_l \leq f(x, z, t_j) \leq y_u], \quad (8)$$

where,  $C(x, z)_j$  ( $\in C(x, z)$ ) is a part of the fluctuation of the factors assigned to the  $j$  th assignable point and holds the following equation:

$$\sum_j C(x, z)_j = C(x, z). \quad (9)$$

When considering the four assignable points, the four swarms are defined and search for the adjustable range (assignable points) based on the VEPSO procedure. The optimization algorithm using the VEPSO is described in Figure 3. In this algorithm, the parameters of the VEPSO (e.g.  $c$ ,  $w$ ,  $T_{\max}$ , etc) are firstly set. Next, the number of the assignable points is decided and the same number of the swarms are set. The locations of the particles are updated based on the objective (robustness)  $R_j$  ( $j=1, 2, \dots, n_{ad}$ ). The update of the locations iterates until  $T = T_{\max}$ , and the global best location of the swarms are derived as an design solution (adjustable range).

Figure 3: Proposed algorithm of robust design method

## Illustrative example

### Problem description

To demonstrate the proposed robust design method, we applied it to a seat design for railway vehicles because numerous people with diverse physiques and sitting postures use these seats. However, the conventional seat design typically assumes an average physique and posture. Thus, designing a seat that is robust for various physiques and postures is desirable. Herein the design objective focused on the hip-sliding force, which is generated on the buttocks by the static instability of the upper and lower body masses, causing discomfort when sitting (Matsuoka 2000). Therefore, the design objective is to inhibit the hip-sliding force for various physiques and postures.

Table 1 defines the objective characteristic and factors of this design. The control factors, seat cushion angle (hereafter called C.A.), seat back angle (B.A.), and forward tilt angle of the upper seat back (F.A.), can be adjusted by the mechanisms for the seat cushion forefront lifting function, reclining function, and forward tilt function, respectively. Previous research (Matsuoka 1988) has demonstrated the influence of these angles on the hip-sliding force. Therefore, these angles are considered AFCs. Noise factors include users' physiques and sitting postures. The physiques are defined based on actual measurements of Japanese citizens (National Institute of Bioscience and Human Technology, 1996). Additionally, we considered three sitting postures: a standard sitting posture where the lumbar region is in contact with the seat back, a stretched waist sitting posture where the waist is stretched and slid forward from the standard sitting posture, and a bent waist sitting posture where the waist is bent and slid forward from the standard sitting posture. The ratio of these sitting postures is 3:1:6 (Matsuoka, 2000).

Modeling the sagittal plane of the human body and the seat was used to derive the objective function (Figure 4). The human model assumes that the movements of the low momentum joints are zero and is consequently, composed of four high momentum joints. On the other hand, the seat model, constructed based on the existing seat found on a 485 train (Hatsukari), is divided into three parts: seat cushion, upper seat back, and lower seat back, which are rigidly linked. Figure 5 shows the objective functions (the formula to compute the hip-sliding force for each posture) derived based on these models. The robustness index ( $R_A$ ) is derived as the weighted sum of the indices calculated using these formulae.

Additionally, in the PSO, the parameters (e.g.  $c$ ,  $w$ , etc) are important for the convergence or the computational efficiency. Therefore, this study implemented some optimizations regarding the recommended values of the parameters in the conventional studies and compared the results to clarify the proper values of them. This study focused both on  $c_1$  and  $c_2$  and conducted the four analyses using the parameter combinations: ( $c_1=2.80$ ,  $c_2=1.30$ ) recommended by Carlisle (Carlisle and Dozier, 2001); (2.05, 2.05) suggested by Kennedy (Kennedy, 1998); (1.55, 2.55) and (1.05, 3.05) that are smaller values of  $c_1$ . This study also implemented the optimization using the traditional genetic algorithm (GA). The definition of the parameters is summarized in Table 2.

Items	Definition
Hip-sliding force (as objective characteristic)	Tolerance of Hip-sliding force: -10 to 20 N.
Seat cushion angle $\theta_C$ Seat back angle $\theta_B$ Forward tilt angle $\theta_F$ (as ACFs)	$10 \leq \theta_C \leq 25$ $20 \leq \theta_B \leq 35$ , $\theta_C + 10 \leq \theta_B$ $0 \leq \theta_F \leq 30$
Body height $L$ Body height $M$ Sitting posture (as noise factors)	$L$ and $M$ are normal distributions Mean value of $L$ : 1.65m, standard deviation of $L$ : 0.08m Mean value of $M$ : 58.1kg, standard deviation of $M$ : 9.09kg Ratio of standard, stretched waist, and bent waist sitting postures: 3:1:6

Figure 4: Model of the human body and seat

Items	Set value				
	GA	Proposed method (Analysis)			
		1	2	3	4
Tolerance of $y$		$-10 \leq y \leq 20$			
Feasible area of $t_1$		$10 \leq \theta_C \leq 25$			
Feasible area of $t_2$		$20 \leq \theta_B \leq 35$ , $\theta_B \geq \theta_C + 10$			
Feasible area of $t_3$		$0 \leq \theta_F \leq 30$			
Max iteration number $T_{\max}$	10000	100			
$c_1$	—	2.8	2.05	1.55	1.05
$c_2$	—	1.3	2.05	2.55	3.05
$w_{\min}$	—	0.4			
$w_{\max}$	—	0.9			
Number of assignable points	2	2 (number of swarms)			
Swarm size	—	20			
Solution number		5			

Table 2: Definition of parameters

## Result

The design solutions (adjustable ranges) derived by the proposed method using the different parameters and by the GA are shown in Figure 6. Additionally, the Euclidean distance between assignable points  $D$  is calculated in order to compare the size of the adjustable range. The average and the standard deviation of the distance are indicated as shown in Table 3. Figure 6 and Table 3 show the adjustable ranges derived by the proposed method are smaller than and assure as same robustness as those by the GA. Particularly, the mean value and the standard deviation of the adjustable ranges derived in analysis 2 are small. This means the values of the parameter ( $c_1 = c_2 = 2.05$ ) are suitable to minimize the adjustable range. This is caused by the two features of the VEPSO: 1) the larger  $c_2$  prevents the global solution search same as the PSO; 2) the larger  $c_2$  encourages the swarms to search the area close to each other. Because of the trade-off relationship between the two features, the same degree of incidence is compromised to be an optimum value in the proposed method.

## Conclusions

In this research, ACFs, which can be adjusted within a given range to increase the robustness, were defined. Additionally, a method to calculate the robustness  $R_A$ , including the objective characteristics adjustment by the factors and to derive an optimum range of the factors is proposed.  $R_A$  indicates the feasibility that the objective characteristic values are within the tolerance at least once by the adjustment of ACFs. A calculation methods for the index, which uses the Monte Carlo method, are proposed. In contrast, the range of ACFs is optimized by the Vector evaluated particle swarm optimization. In the procedure,  $R_A$  is used to evaluate the particles in several swarms, and each particle searches for the optimum adjustable range of ACFs.

The proposed method was applied to an engineering example (seat design problem). In this application, it was confirmed that the proposed method can derive the design solution with high robustness and small adjustable range.

## Abstract

This paper is devoted to discuss the implementation of models, which are inspired by the fly *Drosophila melanogaster* and able to handle open problems in the field of robotics such as attention, expectation and sequence learning. The role of the Mushroom Bodies (MBs) in solving these tasks is analyzed in detail and a unifying plausible biologically inspired model is proposed. The developed neural structure is able to show different capabilities in line with the paradigm of neural reuse. The same neural circuit can be exploited to accomplish multiple tasks showing interesting capabilities such as attention, expectation and delayed match-to-sample. The simulation results here reported suggest at the same time new neurobiological experiments suited to better understand the underlying mechanisms, to verify the hypotheses formulated and to prove the biological significance of the results.

## Introduction

Efforts to build efficient and adaptive machines stimulated a lot of researchers to take inspiration from Nature for designing, modeling and implementing bio-mimicking circuits and systems able to reproduce specific biological behaviors: locomotion, learning, recognition and others. Since the beginning of this scientific wave, which dates back to the early part of the last Century, two main approaches were established. The first one belongs to the field of artificial intelligence; it took the high level capabilities of living beings as starting point and aimed at designing abstract, yet sometimes very well performing computational models. The second one, called connectionism, started from modeling the structure of the brain at different levels of resolution, with the claim that a good model of the low-level topology and function should lead to the emergence of behaviors well mimicking the biological counterpart, even with regard to high-level functions (Rumelhart and McClelland, 1986). Very recently this second research field successfully exploited innovative tools and methodologies from neurobiology and neurogenetics, with an effectiveness impossible to predict only two decades ago. These new tools opened the way to novel insight into the brain and tremendously contributed to unravel a lot of surprising functions of neural tissues. One of these findings is the so-called *neural*

*reuse*. The term refers to a very common property of neural assemblies, i.e. neural circuits established for one purpose are exploited, recycled, redeployed, during evolution or individual development for other different purposes, often without losing their original functions (Anderson, 2010). This research field is widely supported both by physiological observation and by imaging experiments (i.e. fMRI), where in a considerable number of cases especially high-level cognitive functions are involving the concurrent activation of different areas of the brain otherwise (and well known to be) involved in completely different functions. Insects possess a much simpler brain structure than mammals: their brains were miniaturized during evolution in response to constraints like energy consumption. Notwithstanding their much scaled-down brain size, insects are able to show an impressive number of adaptive behaviors, until a few years ago ascribed only to higher animals (Chittka L., 2009): the smaller brain size did not prevent important capabilities. Considering the fruit fly *Drosophila melanogaster*, one of its first-studied forms of learning is related to olfaction. This learning process has been localized in the Mushroom Bodies (MBs), one of the two prominent insect brain neuropiles of the protocerebrum; the other one is the Central Complex (CX). MBs are commonly considered as a model system for the biochemistry and the connectivity of how synaptic networks can form memory and store information. MBs are responsible for both the short-term and long-term component of olfactory memory. Several different experiments demonstrated how, through classical conditioning, flies can associate a meaning to olfactory inputs after pairing them with positive and negative reinforcement signals (Gerber et al., 2004). Compared to the rest of the insect brain, MBs have attracted a lot of attention witnessed by the recent specialized literature, since, besides olfactory processing and learning, recent studies identified MBs as also responsible for other learning processes (Scherer et al., 2003; Liu, 2006) and choice behaviors (Gronenberg and Lopez-Riquelme, 2004; Tang and Guo, 2001; Brembs, 2009). By modeling the MBs as a pool of spiking neurons divided into different lobe systems and introducing the synaptic connec-

tions identified between the MB intrinsic Kenyon cells and the other structures directly involved like Projection Neurons (PN), Antennal Lobes (AL) and the Lateral Horn (LH), it is possible to investigate the emergence of interesting neural activities that can establish specific behaviors shown in flies, like attention (Arena et al., 2012b), expectation (Arena et al., 2012a) and delayed-matching to sample tasks (Arena et al., 2013) that have been recently proposed. The role of MBs in motor learning is also known from fly experiments: in particular the short-term memory component is not obtained if MB plasticity is inhibited in mutant flies. MBs can be modeled as a reward-driven parameter adapter that improves the fly performance while a task like climbing over a chasm is continuously repeated for multiple times (Pick and Strauss, 2005).

This paper revisits a recently introduced low-level model of the fruit fly *Drosophila melanogaster* MBs under the aspect of neural reuse. It will be shown how the same neural structure can concurrently give rise to a number of different adaptive behaviors, which are also encountered in the biological counterpart. Neural reuse in action will be shown referring to behaviors ranging from classical conditioning, to attention, expectation, consolidation and delayed-matching-to-sample. All these last capabilities can be easily transferred to robotic structures for the implementation of real-time adaptive behaviors.

### Neural Reuse Theory

Various general theories were proposed on the overall functionality of the brain. Among them are two main lines of research worth to be considered in the context of this paper: *Massive Modularity* and *Neural Reuse*. The first theory is mainly drawn from Evolutionary Psychology (Sperber, 2001) and claims that brain processing can be studied by decomposing it into dissociable functional components that vary independently of one another (Carruthers, 2006). Indeed this is a very useful approach, especially when it comes to dealing with complex brains: decomposing and localizing modular blocks in some cases allowed focalizing on specific brain functions. On the other hand, the Neural Reuse theory of brain processing appears to be radically different. It starts from the fact that brains are complex dynamical systems. It refrains from the idea to functionally break a complex function in sub-functions and to assign these functions to specific parts, but rather applies a holistic and somehow heuristic approach to brain functions, which has a lot in common with the complex dynamical system theory. It is grounded on the concepts of *network thinking* and pays attention to higher order brain functions as patterns of neural activity emerging from the overall behavior of a complex system, caused by the spatio-temporal, self-organised, synchronized activity of different parts of the brain working as an orchestra. This concept has been recently studied from the physical point of view especially in simple brains, like the one of the worm

*C. elegans*. These studies demonstrated that network theory can topographically and dynamically address brain dynamics, at least in those small neural assemblies (Dunn et al., 2004). According to the complex system approach, brain behavior can be described in the language of Patterns, and it is most powerful when several, particularly higher brain areas are involved. The decomposition approach is powerful when specific, mostly sensory-input related processing can be broken up into specialized functions. On the other hand decomposition can be too restrictive when looking for much higher functions, like learning, decision making, multisensory processing and complex sensory-motor loops. Within this perspective of complex tasks, if multiple brain areas are involved, it directly derives that various behavioral purposes have to be achieved concurrently. This means that the same spatial temporal patterns emerging from one neural lattice are exploited at the same time in multiple behaviors. This is the core of the *Neural Reuse Theory* (Anderson, 2010). This concept appears to be radically different from the massive modularity concept, even if also neural reuse accepts some functional bias within individual brain regions, especially for those dealing with specific sensory features; it poses a specific distinction between the concept of *work* and that of *use* (Bergeron, 2008). The former is related to the fixed low-level functions of specific brain regions whereas the latter refers to the way these workings are arranged together for many different and concurrent uses of those same regions. The concept of neural reuse can be considered in a phylogenetical and ontogenetical perspective: phylogenetically driven, in the sense that evolutionary processes are biased toward using already functioning circuits over introducing new ones; ontogenetically driven, since learning, with the addition of neural wiring, is one powerful possibility to connect different brain regions and creates cross-over associations. Along these lines, the *Massive Redeployment Hypothesis* (Anderson, 2007) assesses neural lattices that are massively re-used in different high-level functions, since they can be connected in different ways, leading to very different functions. We'll try to apply the introduced neural reuse paradigm on a specific example, a multifunctional structure of the insect brain called Mushroom Bodies. Citti and Niven (Niven and Chittka, 2010) already asserted that insect brains have the suitable size to try to investigate neural reuse in action, since in these small brains, the relatively low number of neurons and mainly short-distance connections are candidate elements for neural reuse, even if circuits are composed of different brain areas. For example, a retention of aversive olfactory memory from larvae to adult flies (Tully et al., 1994) suggests a reuse of particular neural structures through metamorphosis. The smaller the brain, the larger the need for neural reuse. Even if anatomical modularity is clearly given in such small brains, it is also true that a lot of sensory-motor behaviors involve different brain sectors. The insect brain thus appears to be a net-

work mainly composed of locally connected circuits, which however are connected through rare, even single-unit made, long-range links. Whereas modularity increases energy efficiency, the presence of long-range connections appears to promote neural reuse. Therefore invertebrates are a suitable class of animals for neural-reuse investigation, and also for finding an expected compromise between massive modularity and reuse.

### Mushroom Bodies: Neurobiological aspects

The MBs of the fruit fly *Drosophila melanogaster* MBs are a paired structure of the protocerebral hemispheres. The most important constituents of the MBs are the 2500 Kenyon cells (KCs) per side which run in parallel from the input-region calyx through the peduncle and, after a bifurcation, to specific appendices, called lobes. These possess roughly the same topology, but are differently connected to the other neural structures. Among them are the  $\alpha - \beta$ - and the  $\alpha' - \beta'$ -lobes. In flies, there is a prominent olfactory input from the antennal lobes into the calices (Masse et al., 2009). Input from other sensory modalities is not topologically identified in *Drosophila*, but the role of MBs in tasks related to vision, decision making and behavioral adaptation have been reported e.g. in Liu et al. (1999) and Tang and Guo (2001). In the insect brain, MBs interact with Lateral Horns (LHs) and Antennal Lobes (ALs). Recent studies have shown that mutations affecting olfactory-memory formation in *Drosophila* also produce distinct defects in visual attention-like behaviors (van Swinderen and Flores, 2007), suggesting that parts of MBs are reused in several different behavioral contexts and across several sensory modalities. MBs and LHs codify the spatio-temporal information coming from the glomeruli of the ALs. Connections between LHs and MBs have been found, whose entity in *Drosophila* is not well known, but in locusts, which produce an inhibitory effect to the MBs neurons (Perez-Orive et al., 2002); in *Drosophila* they are not yet identified. Not anatomically obvious in *Drosophila*, but in honeybees, MBs receive inputs from other sensory modalities but olfaction like vision, gustation and mechanosensation. In flies and bees, the MB lobe region receives information on sugar reward or electric shock through octopaminergic and dopaminergic neurons, respectively. There is an output of the MBs to pre-motor areas of the brain.

A general block scheme of the interactions among the different neural structures involved in the proposed model is depicted in Fig. 1.

Inside the MBs the flow of information is through the Kenyon cells from the calyx towards the lobes. Neuroanatomical studies in *Drosophila* revealed arborizations of extrinsic and intrinsic MB neurons across the peduncle and mainly in the lobe systems. The lobes are the output region of the MBs and also a region for modulatory inputs (Krashes et al., 2009). Intrinsic neurons provide an alterna-

Figure 1: MBs and their interactions with other insect brain centers. MBs, together with the antennal lobes (ALs) and the lateral horn (LH), are the place for odor representation and learning. The presence of axo-axonal connections between the Kenyon cells, feedback connections between the lobes and the AL layer and the reward or punishment signals mediated via octopaminergic (OAN) and dopaminergic (DAN) neurons, respectively, are important elements that allows the emergence of patterns of neural activity responsible for multiple complex behaviours.

tive modulation pathway between different KCs and/or KCs and other protocerebral brain areas. Extrinsic neurons, on the other side, may be able to bind sensory information processed earlier in different lobes before or after any kind of modulation. This is very interesting for our modeling purposes. Very recently, recurrent connections between MBs and ALs have been found (Hu et al., 2010). The presence of this functional feedback from the MBs to the ALs suggests top-down modulation of olfactory information processing in *Drosophila*. The presence of dynamically changing conditions and noise in the environment leads animal to develop attention-like processes. Attention facilitates focusing on the attended events, while filtering out irrelevant information. These interesting processes have been studied in *Drosophila*. In particular, results by Xi et al. (2008) suggest that MBs in flies behave like an adaptive sensory gain controller, allowing the processing of salient cues, filtering out the background noise and distracting signals. More information from neurobiology, essential to develop an efficient, flexible and multi-functional neural model, concerns the presence of axo-axonal connections among the kenyon fibres, whose role could not be clearly unraveled in experiments, but give us the possibility to add to the computational model efficient diffusion phenomena, which are at the basis of the spatial-temporal clustering capabilities.

### Mushroom Bodies: a computational model

The proposed computational model is directly inspired by the MB structure, including top-down connections to the Antennal lobes, the global inhibitory effect of the Lateral Horn and the axo-axonal diffusive connections among the KC fibers. The proposed neural architecture is a two layers recurrent network in which each neuron is an Izhikevich's class one spiking neuron with spike resetting, (Izhikevich, 2003), which offers many advantages over other neuron models from the computational point of view. Neurons are connected through synapses, modeled as first-order dynamical systems which transform the pre-synaptic voltage spike trains into a post-synaptic current. There are sites where learning is added to the basic dynamics of the synapses. These adaptive sites are areas where neural reuse is prominent: reuse exploits the dynamics arising at sites (which correspond to the working sites in (Anderson, 2010)) where learning is not present, but synaptic and neural dynamics concur to the emergence of clusters of neural activity. Learning is implemented through a correlation based, Hebbian rule called Spike Timing Dependent Plasticity (STDP) (S. Song, 2000, 2001) which has been used in different application, including robot learning (Arena et al., 2009). The algorithm acts on the synaptic weights, modifying them according to the temporal sequence of occurring spikes (Arena et al., 2011). An output layer can be added in order to link the behavior of the second layer to a motor or pre-motor area. The developed neural structure, even if inspired by the insect olfactory system, can be used for stimuli of different sensory modalities (e.g visual features can be easily used in robotic scenarios).

The Antennal Lobes model, as shown in Fig. 1, receives input from the olfactory sensory system (i.e. Antennas). We can assume that each AL neuron, when active, codifies the presence of a particular value for a specific feature of the input. Neurons in the ALs are organized in groups, each group presenting the different values of a given input feature. A competitive topology is implemented between neurons within each group, whereas plastic excitatory synapses link neurons belonging to different groups. When the AL layer is stimulated, after a short transient time, only one neuron in each group remains excited, owing to a Winner Takes All (WTA) topology. The ensemble of all the active neurons encodes the presented object. The adaptive connections between groups of neurons bias the network toward temporarily retaining the presented objects through all its features or to reconstruct lacking features in case of incomplete or noisy detection. Non-learning synapses from the AL model to the MB model are randomly established, with a given probability of connectivity. The MB model is made-up of two twin lattices representing the two-lobes system, here called Self Organizing Spiking Layer (i.e. *SOSL1* and *SOSL2*). They have a toroidal geometry, with local excitatory and global inhibitory synapses. Each neuron within them is connected

Figure 2: Time evolution of the neural activity in the Self Organizing Spiking Layer (SOSL) lattice. The network topology allows the emergence of a winning cluster. This example is related to a lattice of 9x9 neurons (represented in the x-y plane) and reports the mean potential of each neuron in the lattice (z axis) evaluated by dividing the simulation in four time windows. The clustering is obtained after 80 ms of simulation.

through fast excitatory synapses with all the neurons of its neighborhood and through fast inhibitory synapses with all the other neurons of the lattice. The main peculiarity of these SOSLs is a spontaneous clustering, due to the competitive topology: information coming from the ALs is compressed into a cluster of spiking activity, which can arise in different positions in the SOSL1 and SOSL2 due to the random connectivity of the SOSLs with the input layer. A typical neural activity leading to the emergence of a cluster in the SOSL is shown in Fig. 2.

Only in the SOSL1, representing the  $\alpha - \beta$  lobes, a slow and delayed diffusion of the neural activity links each neuron to the other neurons of the same lattice, in order to have the possibility to temporally link different clusters. These synapses are subjected to the STDP learning algorithm, that allows discovering and retaining temporal causality among clusters. These connections have the interesting capability to generate, within the SOSL1 layer, expectation and short-term prediction capabilities, whereas the SOSL2 layer has the main function of working as a back-up copy. Feedback connections able to learn link clusters in SOSL1 to the ALs neurons.

The two lobes (SOSLs) are connected to each other through two sets of plastic synapses, one from the  $\alpha - \beta$  lobes to the  $\alpha' - \beta'$  lobes and the other set from the  $\alpha' - \beta'$  to the  $\alpha - \beta$  lobes. It is known from neurobiology that the neurons belonging to the two clusters are morphologically different. Moreover, whereas  $\alpha - \beta$  neu-

rons give information back to the ALs, by that generating a feedback at the sensory stage, the  $\alpha' - / \beta'$  neurons were found to provide no output signals back into the system, but they just receive sensory input in the last place at the level of the calices. Arena et al. (2013) therefore assumed that the information which arrives at these lobes is retained there and used as a kind of backup copy for memory purposes. Further details on the model are reported in (Arena et al., 2012a).

To summarize this paragraph, input coming from the ALs is clustered into feature-based objects. This information is sent, without learning, to the SOSLs where a clustering effect arises in terms of self-organized spiking activity. The SOSLs concurrently integrate the information coming from the ALs in a given time window: in particular after the emergence of a cluster the neural activity of the network is inhibited by the LH wave. Clusters of spiking in SOSL1 are temporally linked, thanks to synapses that are able to learn, and concurrently, a cluster-induced depolarization of the AL layer is emerging like in Fig. 3. Moreover, a cluster corresponding to the previous input provides information on the past experience of the network for sequence learning purposes. One crucial issue is the synchronization between the delay of the synaptic cluster-linking connections in the SOSLs and the LHs induced inhibitory action onset time. The output layer connects the model to a motor or premotor area. Neurons in the output layer are linked to the SOSL neurons through synapses subject to an associative learning.

### Behavioral repertoire

The concept of neural reuse is applied to the MB architecture that is able to show different behaviors in a unique dynamical system.

### Conditioning in MBs

The model works for conditioning purposes exploiting the feedforward processing of the network. Clusters emerging in the SOSL1 after presenting a given input stimulate an output associative output neuron. When a rewarding unconditioned stimulus is given to the network, a Reward Neuron (RN) becomes active. This is connected to the output neuron through a fixed synapse, representing the unconditioned response to the reward. That way the output neuron is forced to fire, and the synapse connecting this neuron to the SOSL1 cluster is trained. The mechanism guides classical and operant conditioning through hebbian learning: the output neuron takes the role of a premotor neuron, in case of applications to tactic or phobic reactions following learned attractive or repulsive signals, respectively, in robotic applications.

### Modeling attention using the Mushroom Body structure

The attention capability was well assessed experimentally by van Swinderen (2011). Attentional capabilities are ob-

tained by exploiting the feedback synapses, which reuse the dynamics formed into the  $\alpha - / \beta$  lobes lattice (SOSL1) to provide an input to the AL layer. The role of feedback connections in the insect olfactory system model has been analyzed by Arena et al. (2011), on the basis of the biological evidences found by Hu et al. (2010). Feedback synapses are updated according to the STDP learning algorithm. When a cluster is elicited in the SOSL1, the synaptic connections between these neurons and those neurons which are firing in the AL (due to the synchronous presence of the corresponding input) are strengthened, according to the Hebbian paradigm. This produces a pre-polarization of the AL layer and acts as a filter for the sensory input, leading to an attention-like phenomenon. Two major aspects are worth mentioning: the first one is that the spatio-temporal dynamics assumed to link the different internal representations of objects in time is modeled as a specific function of the SOSL1 lobe. The second aspect is that the output of the feedback synapses is delayed; the postsynaptic current influences the input layer only after the lobes have been reset via the LHs. This is equivalent to assume that the action of these feedback connections, being focused to enhance attention loops, is able to persist also after the inhibition coming from the LHs. The actual model hypothesizes massive feedback connections from SOSL to ALs neurons, even if a probability distribution could maintain the same performance in case of a large-scale implementation.

### Modeling expectation

During the efforts spent in delivering an MB model able to elicit both traditional odor conditioning features and attention processes, a behavior emerged, which is related to our concept of expectation. Indeed, this capability is not yet found in insects, but nevertheless the computational results can open the way to a new wave of insect experiments in this direction. The MB neural lattice (SOSL1) is reused for creating expectation by means of the set of plastic delayed synapses (providing a kind of second order diffusion effect) linking each neuron of the SOSL1 to the other neurons of the same lattice, in order to have the possibility to temporally link different clusters. These synapses are subject to the STDP learning algorithm, that allows discovering and retaining temporal causality among clusters. Simulation results show that these connections have the interesting capability to generate expectation and short-term prediction features within the SOSL. The plastic feedback connections, present from the SOSL1 to the AL model and exploited for attention, have here a precious role (this can be also considered a kind of reuse) to boost the model performance. Two main functions have been identified: they are useful to create an expectation-based depolarization of the neurons in the ALs and they are also essential to reconstruct the expected object.

Figure 3: Time sequence of evoked winning clusters obtained during memory consolidation. Each plot represents the mean potential of the voltage in a 9x9 lattice in a steady state condition. The role of noise is important to give to the lattice enough energy to allow the rise of a cluster (a) that activates in time the different clusters (b-d) in a previously learned sequence; this consolidates the memory.

### Memory consolidation

By exploiting the presence of noise in the system (Arena et al., 2012a), an interesting property of the network can emerge. In fact, the contribution of noise can be useful to consolidate the acquired knowledge during a resting phase, when the network is not physically connected to any input signal. In this phase that can be thought of as sleeping condition, the network is simulated no longer by real-world signals used for training, but by noise. The simulation aimed at showing this effect consists first of a learning phase, in which the network creates the association between clusters and objects. As discussed in (Arena et al., 2011) at the end of the training phase no physical input is presented at the ALs layer, but it is assumed that the SOSL1 is subject to noise. These disturbances onset transients in the SOSL1 neurons until a cluster will emerge over the others. If this cluster had formerly been trained to represent a given object, this is recalled at the AL layer, like an “evoked object”. An example of sequence of evoked clusters is reported in Fig. 3.

A new learning cycle will then arise, in which not only this object will be consolidated, but also all the other objects expected after this one in an already learned sequence. During this simulation phase, the network is reused: new imagined solutions could also be experienced during this “sleeping phase”; the system could even create new or longer sequences starting from what it already learned during the “awake phase”.

### The delayed matching-to-sample task

The previously introduced model has been extended to include the role of the MB-lobes in solving problems like the delayed matching-to-sample task: the capability to recognize successive presentations of the same object (Arena et al., 2013). For the first time now this behavior directly exploits the presence of two different lobes structures:  $\alpha - \beta$ — and  $\alpha' - \beta'$ —lobes. It is known from neurobiology that the neurons belonging to the two clusters are morphologically different: whereas  $\alpha - \beta$ — neurons give information back to the ALs, by that generating a feedback to the sensory stage, the  $\alpha' - \beta'$ — neurons were found to provide no output signals back into the system, but they just receive sensory input at the level of the calices. It was therefore assumed by Arena et al. (2012a) that the information arriving at these lobes is retained there and used as a kind of backup copy for memory purposes. As presented in the previous section, each lobe is modeled as a toroidal lattice with clustering capabilities. In addition to the delayed feedback synapses from the  $\alpha - \beta$ — lobes to the input layer, and useful for attention capabilities, the lobes are connected to each other through two sets of plastic synapses, one from the  $\alpha - \beta$ — lobes to the  $\alpha' - \beta'$ — lobes and the other set from the  $\alpha' - \beta'$ — to the  $\alpha - \beta$ — lobes. The overall process dynamics develops as follows. Each SOSL network shows a cooperative-competitive dynamics: if excited, the neurons in both SOSL networks begin a competition and, after a transient, only one cluster of neurons will remain active and stable in each lobe. The LH inhibits both networks after every time window. The resetting effects only the soma, but not the spike responses of the synapses; in particular, those ones between the lobes are reinforced when two clusters in different lobes are concurrently active. This creates a positive loop which increases the spiking rate in the SOSL1 active cluster. We assumed also to have a neuron sensitive to the firing activity of the  $\alpha - \beta$ — lobes network to detect this situation. This structure was used in (Arena et al., 2012a) to detect whether the object presented to the input layer remains the same in two subsequent steps. In fact, the successive presentation of a different object does not cause the closing of the loop and therefore prevents any increase of the synaptic activity in the lobes.

### Towards other behaviors

Insect MBs are involved in a lot of different behaviors: we are in the process of integrating most of these behaviors into a unique model. First of all sequence learning, a capacity of bees, can be considered as an iterated form of the expectation process. Moreover, the concept of sameness, found also in the behavioral repertoire of bees, can be seen as an augmented form of the delayed matching-to-sample-task: we are not so far from showing also these features within the proposed architecture. Even more complex behaviors, within which MBs have a clear role as in decision making

(Tang and Guo, 2001) and motor learning, are presently being deeply investigated. We already have working models that can explain each one of these capacities, but our aim is to use as much as possible information from neurobiology to devise a unified model for all of them, as it is done in the biological counterpart.

## Conclusions

Insects show a complex behavioral repertoire and, in recent years, are becoming a reference point in neuroscience. Their tiny brains must serve all the survival operations despite their really small mass: the surprise is that also a lot of behaviors that are summarized briefly in this paper and traditionally ascribed to the brains of higher animals, are experimentally found in insects as well. Mushroom bodies, the most studied neural assemblies in the insect brain, have several times been functionally compared to mammalian brain centers like the hippocampus (because of their involvement in learning and memory) and the cerebellum (for their involvement in motor learning). MBs play an important role in a large number of behavioral capacities and it is apparent that they serve different low- and high-level functions concurrently: therefore, in accord with the theory of neural reuse, MBs are a paradigmatic case of reused neural networks in action. The role of extrinsic neurons appears to be fundamental, some of which have connections to the KC fibers at the level of the MB calices and others at the level of the lobes and at the same time to other brain centers like premotor areas, ALs and LHs. They appear as the natural candidates to exploit the neural dynamics within the MB cells to boost the insect brain functionality.

In this manuscript we presented a model that has been recently introduced, but has been revisited here in terms of multi-functionality and neural reuse. This model was built in a connectionist manner, obeying, although in a scaled version, the neurobiological topology. The model was initially built for showing basic learning and conditioning capabilities; subsequently it was found able to show other interesting behaviors, like attention, expectation, sequence learning, consolidation during sleep and delayed-matching-to sample tasks. All of the just-mentioned features emerge from the same spiking neural lattice, which is reused in different ways. An interesting fact is that, while most of these behaviors were experimentally found in fly experiments, others, like expectation, were not yet considered as a capability of the fly. The fact that the model built here is able to show such additional capacities, opens the way to design experiments for finding these behaviors in flies. This is a win-win example in which neurobiology and computational modeling can mutually help one another to advance knowledge in both fields. There are other complex behaviors that these tiny insect brains are able to show, like decision making, motor learning and so on, in which MBs are known to be involved. Particular efforts are ongoing to see if and to

what extent the actual model might be able to represent also these additional behaviors; these efforts will further enhance our understanding of the concept of neural reuse and multifunctionality.

## Abstract

### Introduction

This abstract aims to present our recent work on exploring the concept of mental imagery and mental simulation as a fundamental cognitive capability applied to robot controllers, with the aim of improving the motor performance of the robot in terms of motor control and multi-degrees of freedom coordination. Indeed we believe that mental imagery models can give the opportunity to apply such behaviour toward the development of artificial cognitive systems, in order to improve robots' motor performance in general and in complex motor planning. This objective can be achieved using bio-inspired computational modelling technologies, such as artificial recurrent neural networks, able to emulate processes of mental training by mental simulation.

In particular, as proof-of-concept, we designed a dual neural network architecture, that allows the iCub to improve autonomously its sensorimotor skills, with techniques inspired by the ones that are employed with human subjects in sports training. This is achieved by endowing a feedforward controller of a secondary recurrent neural system that, by exploiting the sensorimotor skills already acquired by the robot, is able to generate additional *imaginary* examples that can be used by the controller itself to improve the performance through a additional learning process. Moreover we show that data obtained with artificial *imagination* could be used to simulate *mental training* to learn new tasks and enhance their performance. Results of experimental tests in controlling a ballistic movement with the simulator of the iCub humanoid robot platform are presented as evidence of the opportunities presented by the use of artificial mental imagery in cognitive robotics.

### Material and Methods

The neural system that controls the robot is represented in Figure 1(a), that consists of a three layer feedforward network (FFNN) that implements the actual motor controller, and of a Recurrent Neural Network (RNN). The RNN models the motor imagery and it is represented in detail in Figure 1(b). Normalized joint position of shoulder pitch, torso

Figure 1: Artificial Neural Networks: (a) The Dual Network Architecture (FFNN + RNN). (b) Detail of RNN: Red connections are active in *imagery mode* only, while green connections are deactivated in *imagery*.

yaw, and hand wrist pitch are the proprioceptive information for input and output neurons. Another neuron is the grab/release command, respectively with value 1 and 0. All values are normalized in the range [0,1]. We used a classic back-propagation algorithm as the learning process. The learning phase lasted 10000 epochs with a learning rate of 0.2 without momentum. The experimental task is shown in Figure 2(a) and it is the realisation of a ballistic action, involving the simultaneous movement of the right arm and of the torso. It should be noted here that, since ballistic movements are by definition not affected by external interferences, the training can be performed without considering the surrounding environment, as well as vision and auditory information. The task of the robot is to throw a small cube of side size 2 cm and weight 40 grams as far as possible according to an externally given velocity for the movement. The robotic model used for the experiments presented here is a simulation of the iCub humanoid robot, that was developed with the aim to accurately reproduce the physics and the dynamics of the physical iCub using a software library that provides an accurate simulation of rigid body dynamics and collisions.

Figure 2(a) presents the three action phases: (left) *Preparation* phase, the object is grabbed and shoulder and wrist joints are positioned at 90 degrees; (center) *Acceleration* phase, the shoulder joint accelerates until a

Figure 2: Action phases and performance comparison (by means of duration and release point errors) of FFNN and RNN as controllers with full range training

given angular velocity is reached, while the wrist rotates down; (right) *Release* phase: the object is released and thrown away. The experiments are divided into two phases: In the first phase the RNN was trained by a simple heuristic to predict its own subsequent sensorimotor state. To this end joint angle information over time was sampled in order to build 20 input-output sequences corresponding to different directions of the movement. In addition, in order to model the autonomous throw of an object, the primitive action to grab/release was also considered in the motor information fed to the network. In the second phase the RNN operates in *offline* mode and, thus, its prediction are made according only to the internal model built during the training phase.

### Experimental results and Discussion

In our experiments we tested the impact of mental training in action performance in a different speed range that was not experienced before. To this end we split both the learning and testing dataset into two subsets according to the duration of the movement: *fast* range subset comprises examples that last less than 0.3 seconds; *slow* range subset comprises all the others. Figure 2(b) shows the performance of the two nets as controller of the ballistic task. As expected the FFNN is the best controller for the task if the full range is given as training, thus, it is the ideal controller for the task.

To test the mental training, we compared results on three different case studies: (a) **full range**: For benchmarking purposes, it is the performance obtained by the FFNN when it is trained using the full range of examples (*slow* + *fast*); (b) **slow range only training**: The performance obtained by the FFNN only when it is trained using only the *slow* range subset. This case stressed the generalization capability of the controller when it is tested with the *fast* range subset; (c) **slow range plus mental training**: In this case the two architectures operate together as a single hierarchical architecture, in which first both nets are trained with the *slow* range subset, then the RNN runs in *mental imagery mode* to build a new dataset of *fast* examples for the FFNN, that is incrementally trained this way.

Results show that generalization capability of the RNN

Figure 3: Results: Distance reached by the object after throwing movements of varying velocities. Negative values represents the objects falling backward;

helps to feed the FFNN with new data to cover the *fast* range, simulating *mental* training. In fact, the FFNN, trained only with the *slow* subset is not able to foresee the trend of duration in the *fast* range, this implies that *fast* movements last longer than needed and, because the inclination angle is over 90 degrees, the object falls backward (see Figure 3).

The FFNN failure in predicting temporal dynamics is explainable by the simplistic information used to train the FFNN, which seems to be not enough to reliably predict the duration time in a faster range, never experienced before. On the contrary, the greater amount of information that comes from the proprioception and the fact that the RNN has to integrate over time those information in order to perform the movement, makes the RNN able to create a sort of internal model of the robot's body behavior. This allows the RNN to better generalize and, therefore guide the FFNN in enhancing its performance.

### Conclusion

The results presented in this work, in conclusion, allow to imagine the creation of novel algorithms and cognitive systems that implement even better and with more efficacy the concept of artificial mental training. Such a concept appears very useful in robotics, for at least two reasons: it helps to speed-up the learning process in terms of time resources by reducing the number of real examples and real movements performed by the robot. An interesting direction for future work is the integration of the artificial imagery with reinforcement learning techniques, with the aim to improve the learning phase replacing real actions with *mental* simulations.

### Acknowledgment

The work was partially funded by the European Project ROBOT-ERA.

## Abstract

Visual feature detection with limited resources of simple robots is an essential requirement for swarm robotic systems. Robots need to localize their position, to determine their orientation, and need to be able to acquire extra information from their surrounding environment using their sensors, while their computational and storage capabilities might be very limited. This paper evaluates the performance of an experimental framework, in which environmental elements such as landmarks and QR-codes are considered as key visual features. The performance is evaluated for environmental light disturbances and distance variations and feature detection speed is thoroughly examined. The applicability of the approach is shown in a real robot scenario by using e-puck robots. Finally, the results of applying the approach to a completely different setting, i.e., simulation of pheromones using glowing trail detection, are presented. These results indicate the broad applicability range of the developed feature detection techniques.

## Introduction

In recent years there has been a rapidly growing interest in using teams of mobile robots for achieving complex tasks such as environmental coverage (Cortes et al., 2004) and exploration (Burgard et al., 2005). This interest is mainly motivated by the broad spectrum of potential civilian, industrial and military applications of multi-robot systems. Triggered by this interest, today, development of practical approaches for multi-robot problems is a well established topic in multi-robot research (e.g., (Hennes et al., 2012; Ranjbar-Sahraei et al., 2013)).

A natural phenomenon with high relevance to practically applicable multi-robot approaches is the foraging behavior of ants. In ant foraging, ants deposit pheromones on their path, while they are looking for either food or nest, which in long term establishes a path between these two locations (Dorigo et al., 2000). A slightly different foraging behavior can be seen among honeybees. Instead of using pheromones to navigate through an unknown environment, honeybees use a strategy called *Path Integration*, in combination with landmark navigation. These strategies turn out to be highly effective in solving distributed optimization problems (Lemmens, 2011). Although investigation of foraging behavior

of ants and bees is very interesting, the task of locating and acquiring resources in an unknown environment is quite a difficult task in practice (in particular with robots that have limited resources). Considering that the foraging task can be seen as an abstract representation for many other advanced tasks, such as patrolling and routing. A successful embodied implementation of distributed foraging can result in promising applications in, e.g., security patrolling, monitoring of environments, exploration of hazardous environments, search and rescue, and crisis management situations.

Getting motivation from the mentioned potential applications of distributed coordination and following the previous work (Alers et al., 2011; Lemmens et al., 2011), which mainly was relied on random exploration methods and infrared sensor data for obstacle detection, authors have recently introduced a framework for simple swarm robotic systems, which exploits vision in robots with very limited resources to extract information from landmarks and environmental patterns (Alers et al., 2013). These features are used as waypoints to navigate in an unknown environment, locate other entities, and detect modifications made in the environment. Although the previous paper describes the framework in detail, its performance in different environmental conditions, and various scenarios is not studied/compared yet. Therefore, this paper focuses on evaluation of this framework in different environmental settings (various light intensities, and detection distances). The detection speed is also deeply studied in various scenarios. In parallel, a new environmental feature, the glowing trails, is described; the developed approach is adapted to this feature, and the results are illustrated.

The remainder of the paper is structured as follows: First related work is briefly reviewed, then the vision-based framework for robots with limited resources is introduced. As the main contribution of this paper we address the influence of external variables, like environmental lighting conditions and viewing angles, on the detection performance of specific features. Also the reliability of detection of the various features are evaluated, and the overall performance regarding time and memory consumption in respect to us-

ability in real robot scenarios is investigated. Afterwards, the newly introduced feature, the glowing trails, and its application is described. Finally, two different types of swarm robotic implementations of this framework are illustrated, which can also be found online in (SwarmLab, Maastricht University, 2013a,b). The concluding remarks are included at the end of the paper.

### Related Work

Robotic systems use vision for accomplishing various tasks ranging from mobile robot navigation (DeSouza and Kak, 2002) to industrial applications (Gonzalez and Safabakhsh, 1982). However, most of the research in this field is focused on the image processing techniques which need a centralized unit to deal with the computations and memory storage tasks. For instance, (Winters et al., 2000) used a Pentium II 350MHz PC and (Chen and Birchfield, 2006) took advantage of a Dell Inspiron 700m laptop with 1.6 GHz CPU for vision-based mobile robot navigation. (Baeten and De Schutter, 2002) used a vision-based approach for accurate and fast task execution, while all of the computations were carried out by a digital signal processing module, serialized with a host computer.

When vision is required for decentralized units (e.g., robots in a swarm) either, each agent is equipped with relatively powerful resources (e.g., in (Quinlan et al., 2003) the Sony's AIBO robots are equipped with 576 MHz CPU and 64 MB RAM), or has a centralized unit with an overhead camera which processes the image, and sends the required data to the robots (e.g., in (Ranjbar-Sahraei et al., 2012a) a host computer denotes the exact position of robots). Alternatively, (Slusny et al., 2009) used a swarm of e-puck robots in which each robot takes an image individually, sends it to a centralized processing unit via Bluetooth, and receives the required data back from that server.

In contrast to the above mentioned works, being able to process images on a robot with very limited resources is a mandatory requirement for swarm robotic systems. In these systems using centralized units is impossible (due to the complexity and high amount of data). Equipping robots with high capabilities can be very expensive, although recent development of mobile phones can argue against this. Simple micro controllers will always be more cost effective. Therefore, in this paper we use the e-puck robot camera and its internal resources (i.e., a 60 MHz CPU and 8KB RAM) for detection of different features in the environment (e.g., barcodes, and QR-codes).

### A Vision-based Framework for Swarm Scenarios

In (Alers et al., 2013) we explored several visual features that can be used for acquiring information from the environment by a robot with limited computational abilities, equipped with a camera. For detecting key locations in the environment (e.g., corners in a maze), we investigated the

usage of specific landmarks for these locations. Each landmark consists of an upper ring with a solid color, so that it can be detected from a distance, and on the lower part a unique barcode for keeping track of the landmark numbers, as can be seen in Fig. 1a. Furthermore, we explored the possibility to detect markers with an even higher data density: QR-codes, as in Fig. 1b. The challenge in the detection of these two-dimensional codes, lies in analyzing and processing the camera data with the limited processing and memory resources that are available in our robotic platform. Finally, we explored the most common feature already available in every swarm robotic setting: the presence of other robots. It's always favorable to detect the relative distance and orientation to other robots in respect of one's position. Therefore, the available LEDs on the robot provide a very good feature for robot detection from a distance, see Fig. 1c. Moreover, we designed a specific gradient pattern for nearby robot detection, as shown in Fig. 1d, which can result in a very accurate orientation and distance detection.

Figure 1: Detectable features presented in (Alers et al., 2013) (a) Landmarks with barcode. (b) QR-code level 3. (c) Robot LEDs. (d) Robot orientation pattern.

### Performance Evaluation

In this section the features, which were briefly addressed in the previous sections (described in more detail in (Alers et al., 2013)), are evaluated for their usability in real-world settings.

We start by evaluating several image filter techniques that are used to transform the captured image into a more suitable format. After this transition we run several utility functions, to cluster pixels or detect specific patterns. These filters and utility functions are the very basis of the feature detection and will run as a pre-processing step on every captured frame before the image is passed through to the actual feature detectors. Then we will describe the environmental influences and corrections needed for optimal performance under different circumstances. We also evaluate the detection performance based on distance variations of the detectable objects. Finally we give an overview of the time that is needed to detect each feature.

### Filter and Utilities

To see how applicable the filters are in a real robot setup it is important to know whether the filters can be used in

real-time for the specific setup, and whether for this particular setup all filters can be implemented due to the memory constraints of the platform. Therefore, in this subsection we provide time and memory allocation measurements of the provided filters, such as grayscale, Hue, several forms of Halftoning, and Gaussian blur filters. We also provide this information for the (group detection), (pattern finding) and (Hough transformation) utilities, which are described in more detail in (May, 2013). Furthermore, we provide overall detection-time measurements of the robot camera, that is needed to capture images.

**Filters** The various types of filters are the core elements of our feature detection. During the detection of a specific feature, often several filters are needed, and sometimes a single filter is used multiple times in one process. To measure the performance and increase the time measurement accuracies, we run the filters 1000 times repeatedly on one picture, and then divide the overall time by 1000 which gives us the running time for one specific filter. As the filters work independent of the data there should be no influence of the actual image to the measurement results. In Table 1 the average time that each filter needs to process a single image with a resolution of 40x40 pixels is listed, this table also lists the memory requirements for each filter. Looking at the memory requirements it should be noted, that only 8000 bytes are available, and a simple filter iteration can already consume a considerable amount of memory (e.g., a single run of the Halftoning histogram filter requires 3.4% of the total memory).

Filter	Time	Memory
grayscale	17.9ms	6 Byte
Hue filter	31.7ms	20 Byte
Halftoning threshold	3.3ms	2 Byte
Halftoning average	5.9ms	8 Byte
Halftoning midpoint	6.9ms	8 Byte
Halftoning histogram	18.8ms	272 Byte
Gaussian blur	24.4ms	7 Byte

Table 1: Resources used by filters

As can be seen in Table 1, the Hue filter is the most time consuming, this is due to the fact that it converts every pixel to the HSL colorspace. The Halftoning histogram filter is the most memory consuming. On the other hand the Halftoning filter with a specific threshold is the fastest and lowest memory consuming filter, as it needs no pre-calculation and can directly process the image.

**Utilities** The performance of the utilities described in (May, 2013), are more difficult to measure, as they depend on a various number of parameters. Therefore, each utility is evaluated in a separate part. Similar to filters, all utilities,

except for the Hough transformation, run 1000 times on a single image to make a more accurate time measurement.

## I Group Detection

The group detection algorithm locates all clusters of pixels that are non black, and determines their groups center points. The run-time of this algorithm depends on the amount of clusters that are detected, and on the amount of pixels that are included in a group. As can be seen in Table 2, the performance is highly dependent on the number of pixels per group. All processed images have a resolution of 40x40 pixels.

Groups	Pixel per group	Time	Memory
1	1	4.1ms	15 Byte
	9	6.1ms	41 Byte
	25	10.8ms	123 Byte
2	1	4.9ms	15 Byte
	9	8.8ms	41 Byte
	25	16.1ms	123 Byte
3	1	5.3ms	15 Byte
	9	12.5ms	41 Byte
	25	21.1ms	123 Byte
10	160	398.6 ms	15 Byte

Table 2: Resources used by group detection algorithm

Based, on the results in Table 2, this group detection algorithm should only be used in situations, where time is not a critical factor, as we usually deal with detection of about 10 groups.

## II Pattern Finder

There are two pattern characteristics which can influence the performance of the pattern finding algorithm; first the length of the pattern, and second the number of reoccurrences of the pattern in the image. Due to the fact that the pattern finder searches only a single column or row at each iteration, we have to make sure that this row or column is as long as possible. According to the specifications of the camera, the maximum length in vertical alignment is 480 pixels and in horizontal alignment 640 pixels. The latter direction is chosen for the performance measurements. The pattern itself has no influence on the performance, as the image is stored in run-length encoding, but the number of color changes in the pattern do influence the results.

As can be seen in Table 3, the time and the memory consumption mainly depend on the size of the pattern. The second parameter gives the reoccurrence of the pattern in the detection area. In practice this means that the algorithm needs up to 42.3ms, to scan every line of a halftone image with 96x96 pixel. From this we can

Pattern length	Matches	Time	Memory
3	1	2.8ms	33 Byte
	3	2.9ms	33 Byte
	5	2.9ms	33 Byte
9	1	4.0ms	45 Byte
	3	4.0ms	45 Byte
	5	4.1ms	45 Byte
15	1	4.8ms	57 Byte
	3	5.0ms	57 Byte
	5	5.1ms	57 Byte

Table 3: Resources used by pattern detection algorithm

conclude that it is possible to process even large images in an appropriate amount of time.

### III Hough Transformation

We implemented two versions of the Hough transformation, the standard one and the fast transformation. The standard Hough transformation is a time consuming algorithm, which can detect multiple lines. Due to the limitations of the memory of the e-puck, the classical Hough Transformation can not run at the same precision as the Fast Hough transformation, which can only detect one line. Unlike the other utilities presented, the Hough transformation is independent of the image data, it always needs the same amount of time and memory. All tests were done with a grayscale image of 40x40 pixel.

Algorithm	Time	Memory
Hough Transformation	2721.3ms	1800 Byte
Fast Hough Transformation	121.2ms	180 Byte

Table 4: Resources used by Hough Transformation

As can be clearly noted from Table 4, the Fast Hough transformation, reduces the run-time requirements by a factor of approximately 22, and the Memory requirements with a factor 10.

**Camera** In addition to the different filters and utilities, the performance and speed of the camera itself, on the overall performance of the system is measured. Pictures are captured in color, grayscale and halftone mode, and the capture time is computed by measuring the overall time required for capturing 1000 images and calculating the average as shown in Table 5. For color and grayscale images the same picture size is chosen. The advantage of halftone images is their higher data resolution, to accommodate this the resolution of the halftone pictures is higher than the one for color and grayscale.

Just capturing a single image takes much more time than running a single algorithm needed to process the image.

Mode	Size	Time	Memory
Colored	40x40 pixel	153.1 ms	3200 Byte
Grayscale	40x40 pixel	80.7 ms	1600 Byte
Halftone	96x96 pixel	1734.2 ms	2752 Byte

Table 5: Resources used by camera for different modes (i.e., color, gray-scale, halftone)

This can be a downside when a situation requires higher capture details, which can be done by taking multiple images and adding the processed data together. This will lead to higher accuracy, but at the cost of processing time.

### Environmental Light Condition

Light is a part of the environment which is uncontrollable in the real world. Depending on where, and how bright the light sources are, the images taken by the robot differ in their contrast and brightness. The robot's internal camera calibration tries to eliminate the influence of the light, and tries to return the same image for different brightnesses. With decreasing light intensity, it is more complicated for the auto correction to fulfill its task. To evaluate the light conditions we have built a box, which has white walls and is closed on all sides except for the top. This box, as can be seen in Fig. 1c, contains the robot, and the top is closed with a laptop monitor. The monitor acts as a controllable light source and has a constant light distribution of 300 cd/m<sup>2</sup>. In all our experiments we place a detectable feature inside this box and decrease the light intensity in 10 steps of 30 cd/m<sup>2</sup>, from full brightness till complete darkness.

**Landmark** In the first test landmarks are placed in the box. As shown in Fig. 2, the brightness of images is not that much influenced by the light condition. The first five images have almost the same brightness, but the noise density increases. Only in the last image, when the light intensity is completely reduced, the landmark is not recognizable any more.

Figure 2: Detection of landmark for different brightnesses (a) 100% (b) 80% (c) 60% (d) 40% (e) 20% (f) 0%

From the histogram values in Fig. 3 it can be seen that the colors are all moving to the same area. This effect is due to the automatic light gain correction of the e-puck camera. It

influences the brightness in a way, that the average value of all pixels is always the same.

Figure 3: Grayscale histogram of landmark with brightness of the environmental light at (a) 100% (b) 60% (c) 0%

**Robot Detection** In order to examine how the e-puck camera handles the LEDs of another e-puck, we show in Fig. 4 the influence of environmental light on a captured image. Unlike in the images of the landmarks in previous experiment, there are significant differences in these images of this experiment. At 100% brightness, the LEDs cannot be differed from the surrounding environment (see Fig. 4a), but the body pattern is clearly detectable. With low light conditions, as can be seen in Fig. 4f, the LEDs are clearly distinguishable from the remaining image, but the body pattern cannot be detected anymore.

Figure 4: Images taken from an e-puck with brightness at (a) 100% (b) 80% (c) 60% (d) 40% (e) 20% (f) 0%

This effect can also be seen, when the camera zooms in into one of the single LEDs, that was detected in the overall scene. In Fig. 5a the white part of the LED fills only a small part of the image and the single LEDs can be clearly distinguished, while in Fig. 5f the two LEDs are forming one big part.

The influence of the environmental light on the detection of LEDs is very important. In bright environments the probability of detecting this feature is much smaller. In a dark environment, other features, like the body pattern, cannot be detected anymore. An optimal condition could be a light setting similar to the one in Fig. 4d, where the LEDs can be clearly differentiated from the environment and the body pattern still can be detected.

### Feature Distance

In this subsection, we address how reliable the e-puck can detect specific features, and how the detection rate is influenced by the distance to a specific feature. For this test,

Figure 5: Zooming in to a detected LED of an e-puck with brightness at (a) 100% (b) 80% (c) 60% (d) 40% (e) 20% (f) 0%

we placed the robot in a white environment in front of only one detectable feature. The e-puck has to detect the feature and calculate its estimated position. The test is repeated 100 times with different angles and distances to the feature.

**Color Block** In Table 6 the results of running the color block detection algorithms are shown. During the test distance varies from 20cm to 80cm. Distances below 20cm are not taken into account, because the colored block is not visible in such distances.

Distance	Detection rate
20 cm	96 %
25 cm	97 %
30 cm	96 %
35 cm	96 %
40 cm	89 %
45 cm	78 %
50 cm	79 %
55 cm	68 %
60 cm	51 %
65 cm	38 %
70 cm	15 %
75 cm	7 %
80 cm	1 %

Table 6: Test results for colored block of landmarks

**EAN-8 codes** The EAN-8 code is a part of a landmark. As the colored block is also part of the landmark, the EAN-8 detection can benefit from this and it's relative good detection rate. Each time a purple block is detected the robot can be sure that the EAN-8 barcode is located below this block. However, the exact range of the EAN-8 code still has to be detected. The correctness of detecting and decoding the barcode depends on the distance from which the e-puck reads the EAN-8 code, as can be seen in Table 7. Values below

20 cm are not tested as this is the minimum distance to see the whole EAN-8 bar code. Table 7 also shows the correctness of the data after decoding, which is much lower than just detecting a valid pattern.

Distance	Detection rate	Correctness
20 cm	93 %	68 %
25 cm	89 %	58 %
30 cm	70 %	32 %
35 cm	58 %	5 %

Table 7: Test results for EAN-8 codes of landmarks

**QR-Codes** QR-codes provide high density information, but are quite complex to read. For example, one dimensional bar codes just have to be scanned in a line over the image, two-dimensional codes have to be transformed so that they fit in a fixed rectangle, only then it is possible to process them further. Hence, the detection of the outer shape is very important, but also often fails. The higher the QR-version, and thus the number of modules inside the code, the more exact the shape has to be determined. In Table 8 the detection rate of different versions at their optimal distances are listed. All measurements are done from a position right in front of the pattern. The error correction level is set to *H*, the highest possible level. The correctness is only determined in the cases where the code was correctly detected.

**Robot Detection** In practice, the detection of other robots is done with two different algorithms. First the program tries to detect the body pattern of the robot. When this algorithm does not detect any robot, robot localization bases on the LEDs is performed. In Table 9 the detection rate at different distances is listed, as well as the distance estimation. As the LED based detection does not return any distance estimation the value in the third column is only calculated if the e-puck is detected by the body pattern recognition algorithm.

## Overall Performance

Considering all of the in-detail examination, the performance of a feature detection algorithm is a combination of the processing time of the involving filters, utilities, and also image capturing time. The exact time depends on how often each step has to be executed, and if the objects are recognized by the detection algorithms. In Table 10 the overall processing times for the different features are presented.

Version	QR code size	Detection rate	Correctness
1	21x21	80 %	53 %
2	25x25	48 %	5 %
3	29x29	23 %	0 %

Table 8: Light tests of QR-code detection

Distance	Detection rate	Distance estimation
10 cm	100 %	95 %
15 cm	100 %	79 %
20 cm	75 %	60 %
25 cm	84 %	—
30 cm	58 %	—
35 cm	61 %	—
40 cm	52 %	—
45 cm	39 %	—
50 cm	20 %	—
55 cm	9 %	—

Table 9: Distance tests of Robot detection

Algorithm	Time
Colored block	204.3 ms
EAN-8 code	324.1 ms
Single LED	900.0 ms
Three LEDs	2334.8 ms
Body pattern	198 ms
QR-code	3253.0 ms

Table 10: Required time for detection of the features

From these overall feature detection times we can conclude that detecting static objects such as colored blocks and EAN-8 codes in a real swarm robot scenarios is doable. Even detecting a QR-code is possible, as long as the location of this code in the environment is known, as searching for a QR-code, using vision, requires high processing time, and memory.

## Glowing Trails

As an extension to our current framework we introduce a new feature, the glowing trail. Inspired by nature, in which insects use chemicals for indirect communication (known as Stigmergy), researchers are interested in applying stigmergy in multi-robot systems, as well. However, in-field deployment of an indirect communication requires manipulating environment which is not a trivial task. Researchers have recently used a few techniques for accomplishing this task. For instance, chemical materials has been proposed by (Fujisawa et al., 2008). Due to difficulties in implementation and limited extendibility, this approach didn't provide sufficient applicability in swarm scenarios.

As an alternative, glowing trails exploited by (Kronemann and Hafner, 2010), inspired on (Alers and Hu, 2009), and further extended for swarm robotic scenarios by authors (Ranjbar-Sahraei et al., 2013) are easy to set up in laboratory environment and still very efficient. These glowing trails can help robots to communicate indirectly to achieve their goals (e.g., environmental coverage, intruder tracking, etc.). A simple indirect communication is shown in Fig. 6 in which robots announce their territory border by putting

pheromones on the borders (Ranjbar-Sahraei et al., 2012b).

Figure 6: Using stigmergic communication for efficient area coverage proposed by (Ranjbar-Sahraei et al., 2012b) (a) robot on right hand side detected the glowing trail. (b) robot changes its circling direction. (c) robots establish separate territories

For detection of the glowing trails, in contrast to the simple method used in (Kronemann and Hafner, 2010), in which photo-sensors were used to detect glowing trails, the e-puck vision approach as described above can be used. Therefore, we take advantage from the developed techniques for color filtering and pattern recognition which are designed based on the limited resources of an e-puck robot, and still powerful enough to extract information from the trails.

The new glowing trail feature can be seen in Fig. 7. The detected grayscale image is converted to a black-white image with a fixed threshold. The amount of white pixels is determined to see if there is any trail in the image. When the image has more than 1% of white pixels, a Fast Hough Transformation (Gonzalez and Woods, 2002) is performed to determine the direction of the trail, see Fig. 7(b).

For using glowing trails, the floor should be covered by phosphorescent material which absorbs UV light and re-emits the absorbed light at a lower intensity for up to several minutes after the original excitation. Robots should also be equipped with UV-LEDs to emit light to the glowing materials.

Figure 7: New introduced feature: (a) Initial image from a glowing trail received by e-puck camera. (b) Filtered image with a red directional line determined by Hough-Transformation (May, 2013)

### Real World Evaluation

To test the proposed features and algorithms under real conditions we used this framework to implement two different swarm approaches. One approach focuses on using these features and algorithms in path optimization problems as in (Alers et al., 2011), the other swarm approach focuses on area coverage with glowing trails as in (Ranjbar-Sahraei et al., 2012b).

For the path optimization approach we described and implemented our framework in (Alers et al., 2013). We ex-

amined the proposed approach in a real scenario, in an environment as shown in Fig. 8. A video of this performed experiment can be found online in (SwarmLab, Maastricht University, 2013b), including the intermediate image data from the robot.

Figure 8: Scenario for validation of proposed approach

For the coverage approach, we used the new glowing trails framework extension, introduced in previous section. In (Ranjbar-Sahraei et al., 2013), we demonstrated an implementation of this approach, the results of applying this vision-based trail detection on a real swarm of e-puck robots is shown in Figs 9a- 9c. A video of the performed experiments can be found in (SwarmLab, Maastricht University, 2013a).

Figure 9: Vision-based detection of glowing trails approach

### Discussion, Conclusions & Future Research

In this paper we presented an in-depth study of a vision-based feature detection framework for multi-robot scenarios. This study covered a complete range of performance evaluations, ranging from measuring detection rate for different environmental brightnesses and detection distances to detection accuracy for different features. Furthermore, various experiments on a real e-puck robot were performed to measure the required time for different tasks such as applying gray-scale filter, halftone filter, group detection, and pattern finding algorithms.

From the overall performance measurements we can conclude that detection of objects that are not too complex is easily doable. However, the detection time, and the required memory increases drastically when more complex objects are chosen as features. Moreover, we showed that the environmental light variation doesn't affect the detection of the

features, except in the extremes when it is either too bright or too dark. The detection of other robots via their LEDs is doable in a static situation, but in most swarm scenarios the robots move continuously in the environment, which makes detection of moving robots an open research question in our research. Moreover, for the newly introduced glowing trail feature we demonstrated a working dynamic multi-robot scenario, which encourages us to investigate applications in dynamical swarm-optimization settings. Finally, we as the main future work, we are working on integration of the proposed techniques with the bee-inspired foraging algorithms, where the big challenge in this is to fit all foraging and vision algorithms within the limited memory of the robot.

## Abstract

We propose an approach to the automatic synthesis of robot control software based on the finite state machine (FSM) formalism. In our previous research, we have introduced Boolean network robotics as a novel approach to the automatic design of robot control software. In this paper, we show that it is possible to leverage automatically designed Boolean networks to synthesize FSMs for robot control. Boolean network robotics exhibits a number of interesting properties. Firstly, notwithstanding the large size of the state space of a Boolean network and its ability to display complex and rich dynamics, the automatic design is able to produce networks whose trajectories are confined in small volumes of the state space. Secondly, the automatic design produces networks in which one can identify clusters of states associated with functional behavioral units of the robots. It is our contention that the automatic design of a Boolean network controller can be a convenient intermediate step in the synthesis of a FSM, which offers the advantage of being a compact, readable, and modifiable representation. In this paper, we show that clusters of states traversed by network trajectories can be mapped to states of a FSM. We illustrate the viability of our proposal in two notable robotic tasks, namely collision avoidance and sequence recognition. The first task can be achieved by a memoryless control program, whilst in the second the robots need memory.

## Introduction

The automated design of compact high-level representations of control software for robots is a challenge in artificial intelligence. Through methods of automatic design, a robot learns a behavior without the explicit intervention of the developer. Automatic design methods offer advantages with respect to manual methods in terms of robustness and generality of the design process. Moreover, the space of solutions explored by automatic techniques is larger and less constrained than that explored by methods of manual design (Koza et al., 2003; Lipson, 2005). However, the effectiveness of automatic methods depends on a number of aspects such as the definition of the search space and the existence of a predictive simulation of the system. Yet, such methods do not provide guarantees on the solution optimality. Automatic design techniques act iteratively on the robot

control software in order to reach a configuration that fulfills the requirements. There exist several ways of representing control software of robots, but the finite state machine (FSM) formalism is the oldest and is broadly used.

Our intention is to propose a new way to automatically design FSMs representing control software for robots. The new approach exploits the work carried out in our previous research in the field of Boolean network robotics (Roli et al., 2011) as an intermediate step in the automatic design of FSMs. In the following, we first give an overview of the existing methods for the automatic design of robot control software and then we introduce the original contribution of our work.

Among the existing approaches to automatically obtain a FSM of a control software, evolutionary programming is one of the most notable (Fogel, 1962, 1993). EP is a paradigm used for the generation of programs, code, algorithms and structures in general, by means of variation and selection mechanisms inspired by natural evolution. Although EP was shown to produce interesting results in many important applications, several issues are still open about its employment (O'Neill et al., 2010). One of the main issues is the choice of the most appropriate representation for the programs to be evolved. In fact, the most suitable representation and the appropriate encoding of the programs into individuals in the evolution process are critical aspects for the performance of EP (Petrovic, 2007). Moreover, EP normally requires the definition of constraints to contain the size of the FSM.

Besides the evolution of FSMs, most of the effort in the field of automatic design of robot control systems has been concentrated around artificial neural networks (NNs) (Nolfi and Floreano, 2000). While NNs offer advantages such as high plasticity and adaptability, they are black-boxes and it is often very difficult to analyze their dynamics. The dynamical behavior of a NN can be modeled by a system of differential equations. There exists a number of works that show how the mathematical tools of dynamical systems theory can be used to gain significant insight into the dynamics of small continuous-time recurrent neural networks (Beer, 1995; Ya-

mauchi, 1993; Yamauchi and Beer, 1994). However, when the number of neurons is greater than a few units, the analysis becomes too complex to handle and only qualitative or approximate studies are possible.

In our previous work (Roli et al., 2011), we have introduced Boolean network robotics as a novel approach to the automatic design of robot control software. Boolean networks (BNs) are a model of genetic regulatory networks (Kauffman, 1969). BNs are extremely interesting from an engineering perspective because of their ability to display complex and rich dynamics, despite the compactness of their description and the simplicity of their implementation. BN dynamics can be studied through traditional dynamical system methods (Bar-Yam, 1997; Serra and Zanarini, 1990). The use of concepts such as state space, trajectories and attractors, combined with the discrete nature of BNs, enables non-trivial analysis of the dynamical behavior. Such ease of analysis is one of the strengths of BN systems.

In this paper, we continue the line of research in Boolean network robotics showing that the automatic design of a Boolean network controller can represent an intermediate step in the synthesis of a FSM. The intuition stems from the analysis we carried out on the trained Boolean networks and two interesting properties it revealed. First, the automatic design shapes the network dynamics in very limited volumes of the state space. Second, such dynamics are structured in sets of clusters of states associated with functional behavioral units of the robots. On the basis of such properties, we propose a heuristic to map those clusters into states of a FSM, which offers a compact, readable, modifiable, and formally verifiable representation.

In this work, we propose a proof of concept of our proposal applying Boolean network robotics to two robotic tasks, i.e., corridor navigation and sequence recognition. The first task is a typical collision avoidance behavior and consists in moving along a corridor avoiding walls and objects; this task can be attained by a robot equipped by a memoryless control software. Conversely, the second task presents a sequence-recognition scenario (Sun and Giles, 2001). The complexity of the target task lies in the fact that it requires the robots to have memory of the past in order to choose the next actions to perform.

The analysis of the trained networks confirms the two properties mentioned and allows for simple mapping between clusters of states in the state space of a BN and states of a FSM.

Despite the simplicity of the two tasks, this work represents a first crucial step towards the definition of an automatic design method of FSMs that exploits Boolean network robotics as a convenient intermediate step.

### Boolean network robotics

In this section we first introduce BNs and then we describe how they are employed and configured to let robots perform

the desired tasks.

### Boolean networks

A Boolean network is a discrete-state and discrete-time dynamical system. Its structure is defined by an oriented graph with  $N$  nodes each associated to a Boolean value  $x_i$ ,  $i = 1, \dots, N$ , and a Boolean function  $f_i(x_{i_1}, \dots, x_{i_{K_i}})$ , where  $K_i$  is the number of inputs of node  $i$ . The arguments of function  $f_i$  are the Boolean values of the nodes whose outgoing arcs are connected to  $i$ . The state of the system at time  $t$ , with  $t \in \mathbb{N}$ , is defined as the vector of the  $N$  Boolean values at  $t$ . The state space size is  $2^N$ . Several update schemes can be defined (Gershenson, 2004), but the most studied is characterized by synchronous and deterministic operations.

BN dynamics can be studied by means of the usual dynamical system methods (Bar-Yam, 1997; Serra and Zanarini, 1990), hence the usage of concepts such as state space, trajectories, attractors and basins of attraction. Recently, the attention of the scientific community has focused on the employment of efficient mathematical and experimental methods for analyzing network dynamics and thus have insight into the behavior of a BN system (Fretter and Drossel, 2008; Ribeiro et al., 2008; Serra et al., 2007).

### BN-Robot coupling

To design a BN-based robot control system, we first need to couple the BN to the robot so as to let the BN dynamics guide the robot behavior. For this purpose, some nodes of the network are given special roles. More precisely, we define a set of input nodes and a set of output nodes. This choice characterizes our approach with respect to most of the work performed about BNs, in which they are considered as isolated systems, even though some notable exceptions exist (Ansaloni et al., 2009; Dorigo, 1994; Kauffman, 1991; Patarnello and Carnevali, 1986). The Boolean values of the input nodes are not determined by the network dynamics, but they are imposed according to the robot sensor readings. Similarly, the values of the network's output are used to encode the signals for maneuvering the robot's actuators. Several ways to define the mapping between sensor readings and network's input, and between network's output and actuators are possible. However, the most natural way is to define the mapping via a direct encoding. Figure 1 shows the coupling between BN and robot.

### Automatic design methodology

Once a mapping between the BN and the robot is defined, the BN must be designed in order to control the robot's behavior. Our approach consists in treating BN design as a search problem. In fact, the design of a BN that satisfies given criteria can be modeled as a constrained combinatorial optimization problem by properly defining the set of decision variables, constraints and the objective function.

Figure 1: The coupling between BN and robot.

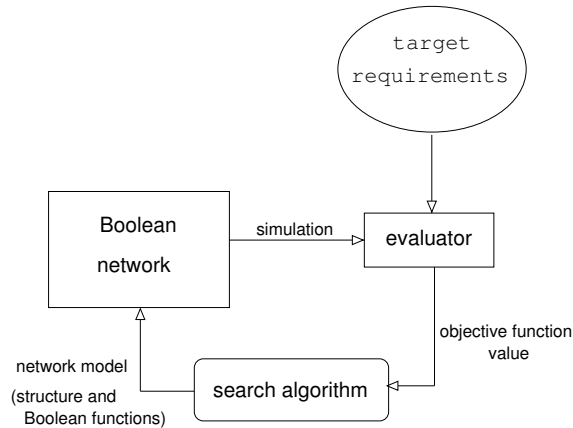

Figure 2: BN design process.

The search algorithm manipulates the decision variables which encode structure and Boolean functions of a BN. A complete assignment of these variables defines an instance of a BN. Then, we couple this network to the robot through the input-output mapping, and subsequently we execute the network. The evaluation of the network at each iteration of the search process is performed in a batch of simulated experiments. The performance of the robot in each experiment is assessed according to a user-defined objective function, which associates the robot behavior to a numeric evaluation. Finally, the search algorithm exploits this value of performance to proceed with the design process. In particular, the algorithm changes the configuration of the decision variables so as to find networks with better performances. This process is depicted in Figure 2.

### Robot tasks

We addressed two test cases with different characteristics: the first, corridor navigation, is a memoryless task while the second, sequence recognition, requires memory. It is interesting to analyze how the nature of the task influences the organization of the state space in the trained networks. In particular, our analysis aims to determine whether the state space of the trained networks exhibit the same properties independently of the nature of the task. These properties, which are (i) the compression of the dynamics in limited regions of state space, and (ii) the organization in clusters of

Figure 3: Corridor navigation environment.

states associated with behavioral units of the robots, enable the exploitation of the trained networks as intermediate step in the synthesis of FSMs.

In the remainder of this section we present the working environment and describe the two test cases.

### Robot and Simulator

For both test cases, the robots are trained in simulation. The simulation framework we employed is the open source simulator ARGoS (Pinciroli et al., 2012). ARGoS is a discrete-time, physics-based simulation environment that provides a faithful simulation of the behavior of different robotics platforms.

The robot simulated in our test cases is the *e-puck* (Mondada et al., 2009). The *e-puck* is a small wheeled robot, designed for research and educational purposes. It has a cylindrical body of 7 cm of diameter, equipped with a variety of sensors. For our test cases, we use the 8 infra-red proximity sensors placed along the circular perimeter of the robot and the 3 infra-red sensors pointed directly at the ground in front of the robot. The 3 latter sensors can be used to detect the color of the ground, in greyscale. The actuators utilized, besides the motors of the two wheels, are the 8 red LEDs.

### Corridor navigation

The first test case is designed to explore the features of networks able to perform a memoryless task. It consists of a robot that must navigate along a corridor avoiding any collision with the walls and finally reach the exit.

**Environment:** it consists of a straight corridor of 6.5 m in length and 1 m in width.

**Task:** at the beginning, the robot is placed within the corridor 6 m far from the exit. During the experiment, the robot must advance along the corridor, avoiding collisions and finally, within the given total execution time  $T = 120$  s, reach the exit. See Figure 3 for a representation of the environment at the beginning of the experiment.

During the execution, if a collision between the robot and the walls of the corridor occurs, the experiment is immediately stopped.

**Performance measure:** the performance assigned to the robot is simply its final distance from the exit (normalized). The smaller is this distance, the better is the performance of the robot.

**BN-robot setup:** for successful navigation, the robot needs the 8 proximity sensors to detect the walls and avoid them.

At each time step, the readings of the 8 sensors are encoded into the values of the BN input nodes. We use 4 input nodes to encode the readings of the proximity sensors. Thus, the 8 proximity readings are gathered in pairs. If at least one of the two sensors of the pair exceeds a chosen threshold, the corresponding input node value is set to 1. The pairs are formed to allow the robots to detect walls in the four directions north-east, south-east, south-west and north-west.

Once the readings of the sensors are encoded in the input nodes, the network's state is updated and finally the values of the output nodes are read, decoded and utilized to set the actuators. We use two output nodes to set the wheel speeds either to zero or to a predefined, constant value.

For this test case, we set the network size to 20 nodes. We leave the analysis on how this value affects performance for future investigation.

**BN design:** the initial topology of the networks, i.e., the connections among the nodes, is randomly generated with  $K = 3$  (i.e., each node has 3 incoming arcs) and no self-connections, and it is kept constant during the training. The initial Boolean functions are generated by setting the 0/1 values in the  $f_i$  uniformly at random. Our search process, which is a stochastic descent, works only on the Boolean functions. In particular, at each iteration, the search algorithm changes the configuration of the network by flipping one bit of the Boolean functions. The flip is performed by changing a random entry in the  $f_i$ , where  $i$  is a randomly chosen node. The new configuration is accepted if the corresponding BN-robot system has a performance at least equal to the current one. The evaluation of each network is performed on a set of initial conditions, that form the training set. For this test case, the training set is composed of six different initial orientations of the robot. The six angles are chosen so as to have six equally spaced orientations in the range between  $\frac{\pi}{3}$  and  $-\frac{\pi}{3}$  (with 0 that is the straight direction of the robot towards the exit). In this manner, the robot must be able to cope with a wide range of different situations and avoid the walls it detects in any direction. The final evaluation assigned to the robot is computed as the average of the performance across the 6 trials. We executed 100 independent experiments, each corresponding to a different initial network. In each experiment, we run the local search for 1000 iterations.

### Sequence recognition

The second test case aims to explore the properties of networks able to perform a task that requires memory. The task is sequence recognition (Sun and Giles, 2001). In particular, the robot must learn to recognize a sequence of colors by performing certain actions. This kind of task is more complex than the previous one, because the robot needs a form of memory to be able to choose the next action depending on the past.

**Environment:** it consists of a straight corridor of 7 m in

Figure 4: Sequence recognition corridor environment.

length and 1 m in width. Along the corridor, the ground is painted to form a striped pattern with three different colors: white (W) represents the background, while black (B) and gray (G) are the symbols of a sequence to be recognized.

**Task:** at the beginning of the experiment, the robot is placed within the corridor 6.5 m far from the exit. During the experiment, the robot must move along the corridor and reach the exit. Every time the robot encounters a black or gray area in the right sequence, it must turn its LEDs on. Conversely, when the robot encounters the background color or other colors in the wrong order, it must keep its LEDs off. The sequence to be recognized is a cyclic repetition of black followed by gray. By performing the right sequence of actions while moving along the corridor, the robot must be able to reach the exit within the given total execution time, fixed in  $T=130$  s. Figure 4 represents an example of the environment at the beginning of the experiment.

In the environment depicted in Figure 4, the robot must perform the following sequence of actions to achieve the goal (omitting the background color (W) whose corresponding LED correct status is always OFF):

Colors along the corridor					
B	B	G	G	G	B
ON	OFF	ON	OFF	OFF	ON
Robot's LEDs correct status					

If the robot, at any instant in time during the execution, performs the wrong action, the experiment is immediately stopped.

**Performance measure:** The performance assigned to the robot is the final distance from the exit of the corridor (normalized between 0 and 6.5). The value must be minimized.

**BN-robot setup:** for this task, the robot needs the ground sensor to detect the color of the ground. For our simple application we use only the central sensor. Since we encode three values (W, B, G), at each time step, the reading of the sensor is encoded into the values of two BN input nodes. We use four nodes to encode the proximity sensors that, even though not strictly needed for the task, can be still useful for the navigation along the corridor.

After the network's state update, we decode and use the values of the output nodes to set the actuators. Besides the two nodes used to control the wheel speeds, an additional output node is utilized to set the state of the LEDs either to ON or OFF.

For this test case we increased the network size to 30 nodes.

**BN design:** initial topology and Boolean functions are randomly generated with  $K = 3$ . In our experiments, the search strategy is a stochastic descent and works only on the Boolean functions, leaving the topology unchanged. The evaluation of each network is performed on a set of initial conditions. More precisely, the training set is composed of 10 different randomly generated sequences of colors on the ground. Differently from the corridor-navigation case, the robot starts always pointing towards the exit. In this way, the navigation task is simplified so as to focus the complexity on the sequence recognition. The final evaluation of a robot is the average value of the performance across the 10 trials. Due to the high computational cost required by each experiment, we executed only 30 independent experiments with 30 different initial networks for 100000 iterations of the search algorithm.

### Analysis of the results

The analysis of the results obtained in both test cases reveals two properties. First, the dynamics of the automatically designed networks spans across a very limited region of the whole potential state space. This means that the search algorithm moves towards networks whose dynamics are compact. This relationship between the design process and the dynamical features of the networks is notable: the search algorithm acts directly only on the network structures, searching for a good behavior of the BN-robot systems while ignoring the dynamics property of the networks. Nevertheless, the analysis shows that the algorithm shapes and compresses indirectly the dynamics of the networks.

The second property observed is the organization of the state space traversed by the final networks in a set of clusters of states, each devoted to perform a specific series of actions.

In the remainder of this section we present the analysis and the results obtained for both test cases.

#### Corridor navigation analysis

Once the design process is completed, the focus of the study is on the dynamical features of the resulting networks. The first aspect we analyzed is the measure of the fraction of state space utilized by the trained networks. In order to carry out this analysis, we collected a large number of trajectories, corresponding to different initial conditions, for each BN obtained. Then, we counted the number of different states that each network traversed across all the trajectories and we reported the empirical cumulative distribution of the resulting values. Figure 5 shows the distribution for the corridor-navigation test case.

The plot shows that the final network dynamics traverse limited volumes of the state space. In fact, the median usage of state space in the 100 trained networks is located around 150 states. This is a very tiny fraction of the whole potential space, whose dimension is  $2^N$  ( $2^{20}$  in this case). This first property enables an analysis of the network dynamics that

Figure 5: Empirical cumulative distribution function of the number of visited states in final networks. Corridor-navigation test case.

allows to gain significant insight into the behavior of the BN-robot systems.

To analyze the organization of the dynamics of a BN controlling a robot, we collected its trajectories by simulating the experiment. Then, we gathered the trajectories and we generated the graph of the observed state transitions. For lack of space, the graphs can be found as on-line supplementary material (Garattoni et al., 2013).

The state space of the robot performing corridor navigation can be decomposed in three macro areas. One is responsible of the behavioral units that react to walls detected on the east side of the robot. Likewise, another cluster of states is devoted to avoid the obstacles on the west side of the robot. Besides, the two areas are both connected to a third cluster, responsible of moving the robot straight ahead as long as no obstacle is detected. Furthermore, it is possible to observe that each cluster of states contains few topical states, visited many times, and a series of other nodes gradually increasing in number and decreasing in visits. To verify this property, we performed the analysis of the graph for all the final networks of the corridor-navigation test case. We report in a plot the cumulative distribution of the fraction of states visited at least  $v$  times, where  $v$  is the number of visits on the x-axis. The results, showed in Figure 6 for a typical case, suggest that the dynamical behavior of a BN is built around few, prominent states that correspond to the main traits of the robot behavior.

The observations and the analysis presented so far suggest a procedure for deriving a representation of the robot's dynamics in the form of a FSM. We determine the states of the FSM by starting the observation from the topical states and gradually moving to the less important ones. The result is that a state in the FSM takes the place of a clusters of connected states in the state space in which the BN remains until

Figure 6: Distribution of the fraction of states visited at least  $v$  times. The fraction is computed with respect to the total number of states visited in 200 runs of 120000 time steps each. Corridor-navigation test case.

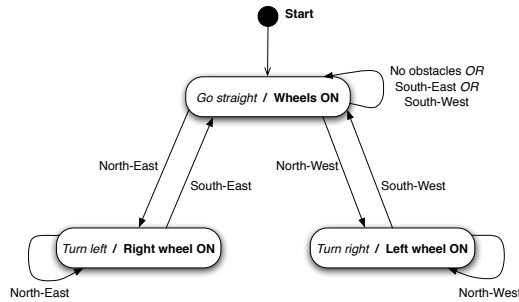

Figure 7: Finite state machine of the state space graph. Corridor navigation.

a specific input is received. By following this simple heuristic for a typical case of corridor navigation, we derived the FSM in Figure 7. We can observe that the automaton corresponds to a very simple yet effective behavior: the robot goes straight until an obstacle is detected on one side; in that case, the robot turns to the other side.

### Sequence recognition analysis

The analysis carried out for the second test case is similar to that presented for the corridor navigation test case. Due to the higher complexity of the sequence-recognition task with respect to the corridor navigation and the important computational cost required by each run, the number of successful networks to analyze is much lower than in the first test case. However, the analysis confirms the same properties.

The number of states visited by the trained networks is very low: the state space usage is on average 200 states out of  $2^{30}$  potential states. By collecting the trajectories of the successful networks and generating the correspond-

Figure 8: Distribution of the fraction of states visited at least  $v$  times. The fraction is computed with respect to the total number of states visited in 200 runs of 130000 timesteps each. Sequence-recognition test case.

ing graphs of the observed state transitions, we observe that the limited region of state space utilized is again organized in sets of clusters of states. The graph derived in a typical case of sequence recognition can be found as supplementary material (Garattoni et al., 2013). At the top of the graph, a set of nodes allows the robot to navigate on the background with its LEDs off until the first colored stripe is found. Then, two clusters of nodes are responsible of the next action, depending on the detected color (turn LEDs on if black, turn LEDs off if gray). Once the first color has been recognized, the BN goes into a new region, dual to the first. Here, we find another area for the background color and two clusters of nodes for the black and gray with actions swapped with respect to the first region. When also the second color is recognized, the dynamics return back to the first area, reusing the same states to recognize a sequence of any length. This analysis shows that the memory, in our case the last color recognized, is stored in the state space in which the BN operates.

Similarly to the corridor-navigation test case, each cluster of states is devoted to the execution of a particular functional behavioral unit of the robot. To support the observation and show that each cluster unfolds around few topical states and a series of other nodes gradually less important, we report in a plot the distribution of the fraction of states visited at least  $v$  times. The results for a typical case of sequence recognition are depicted in Figure 8.

The properties discussed so far allow the employment of the same heuristic used for the first test case to obtain a compact FSM representation of networks performing sequence recognition. From the graph described, we derived the FSM shown in Figure 9.

From the comparison of the FSM in Figure 9 and the one

Figure 9: Finite state machine of the state space graph. Sequence recognition.

in Figure 7, it is possible to notice the influence of the different nature of the two tasks. The interesting aspect to highlight is the representation of the memory required by the sequence-recognition test case. In the corridor-navigation FSM, the action executed by the robot at each instant in time is determined only by the current observation of the world. This is due to the fact that corridor navigation is a memory-less task in which the robot is not required to keep memory of the past but it can simply react to the current stimuli of the environment. On the contrary, the FSM performing sequence recognition can activate different actions, e.g. LEDs on or LEDs off, for the same observation, e.g. the detection of the black color, depending on the previous state. Therefore, the memory that the robot needs to keep track of the last recognized color is stored in the phase space in which the BN operates. More precisely, the memory of the past is represented by the area of state space utilized by the network at a certain time, which is function of all the previous robot-environment interactions.

## Conclusion

In this paper, we have exploited the properties of the automatic design of BN-robot control software to synthesize FSM representations of the robot program. This result has been made possible by an analysis performed on the state space of the best networks obtained at the end of the design process. In particular, the exploration revealed two crucial properties: (i) the trajectories of the BNs controlling the robots are confined in very small areas of the state space and (ii) the dynamics are organized in clusters of states occupy-

ing different areas of the state space, each corresponding to a different set of actions to perform. These results allowed us to outline a procedure to derive a compact view of the best performing network behaviors in terms of FSMs.

A major advantage of this method over current automatic design of FSM controllers for robots is that it does not require any assumption on the number of states nor conditions on the transitions between states. This implies that the behavior of the robot is automatically segmented, i.e., the actions composing the robot's behavior do not need to be specified *a priori*. We would like to emphasize that the use of BNs makes it possible to exploit the properties of both NNs and high level representations like FSMs. In fact, most NN-based robot programs define a mapping between sensor readings and actions on the actuators and thus operate as low-level, fine grained programs which are particularly effective in reactive systems. Conversely, FSM control software is usually based on high-level actions and it is suitable for modular control programs which can be also formally verified. With BN robot programs we can combine both characteristics, as BNs can indeed operate low-level and, at the same time, enable the designer to manipulate a FSM description of the robot control software.

The work carried out for this paper is only a first necessary step towards the application of the proposed approach to more complex and demanding tasks. Future work will focus on improving the performance of the design process and defining an automatic method for synthesizing FSMs starting from Boolean networks. These steps are required for a fair comparison of the proposed approach with existing and well refined design methods.

Of course, the approach has also some limitations. First of all, it requires to deal with Boolean inputs and outputs, which could be sometimes problematic. In addition, the FSM is derived by collecting samples of BN trajectories and a trade-off between precision and computational complexity has to be found.

## Abstract

This paper describes the use of molecular programming techniques to build synthetic *in vitro* and spatially distributed reactions networks with tailored topologies. The basic workflow is to use synthetic DNA strands to encode the topologies of molecular interactions of the reaction network. The actual dynamic of the system is provided by enzymatic reactions controlled and templated by these DNA strands. Here we focus on the implementation of a molecular predator-prey ecosystem. We thus create two autocatalytic DNA amplifications reactions and connect them through predation – the second DNA-species consumes the first one to fuel its growth. We also ensure that these species have a limited lifetime in the test tube. We are therefore able to detect sustained oscillations of the two molecular species, as predicted and observed for real ecosystems. This is the first time that predator prey oscillations are observed in a chemical system. We further expand the analogy between chemical and animal networks by introducing additional interactions such as symbiosis, the mutually beneficial interaction between two species. Interestingly, competition also arises quite naturally from the physical substrate that is used in the modeling process and displays remarkable dynamic consequences such as synchronization or chaos. Finally we report the construction of spatially distributed chemical ecosystems, and the observation of their spatiotemporal behaviors, in particular traveling and spirals dual waves of molecular hunts.

## Introduction

Molecular programming techniques based on synthetic DNA are currently opening unprecedented opportunities for the exploration of molecular informational systems. Because DNA allows easy encoding of molecular interactions and possesses a rich biochemistry, it is possible to reproduce, in test tubes, some of the most fundamental dynamic motifs of biological regulation circuits, like oscillators, bistable switches, etc. (Montagne et al. 2011; Kim & Winfree 2011). This synthetic approach provides a unique opportunity to i) better understand the structure/function relationships at the level of biological circuits; ii) use such molecular devices (computers, controllers, memories, filters ...) into informational chemical systems; and iii) design artificial molecular systems integrating more and more life-like features.

We recently went one step further by demonstrating that molecular programmers need not restrict their inspiration to cellular circuits. Other networks, such as those formed by interdependent species (ecosystems) can also be reproduced

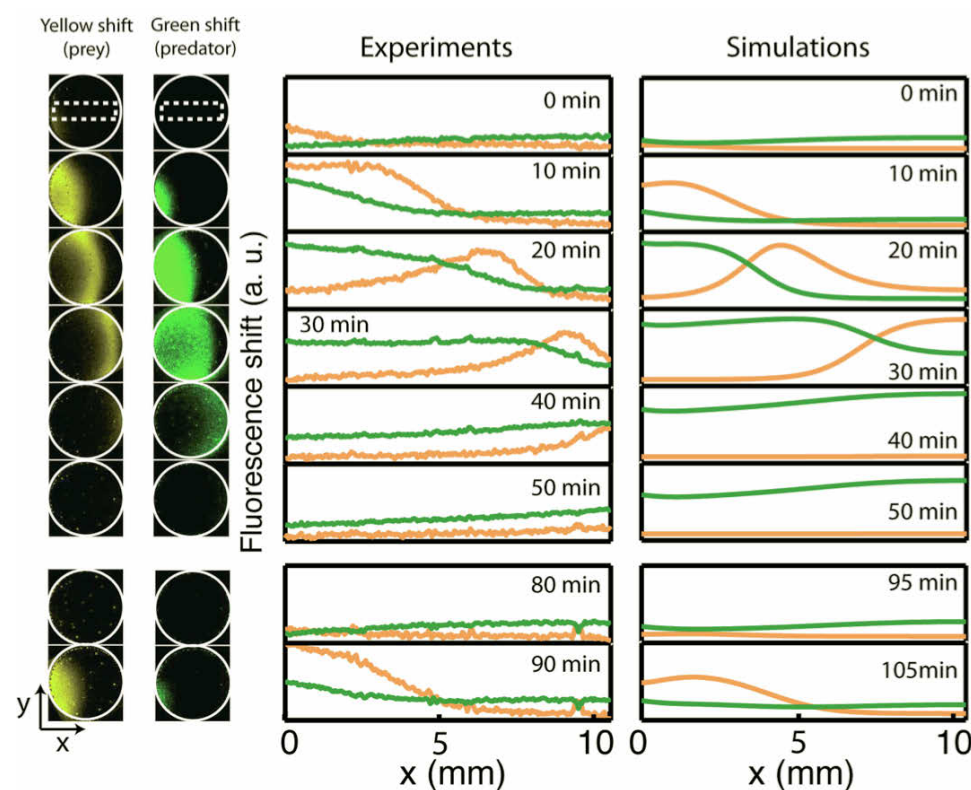

using molecular tools. Our demonstration is based on the predator-prey example, the basic motif of many ecosystems. This particular motif is well known because, somewhat disconcertingly, the simple interaction between a prey and its predator typically leads to sustained oscillations of both populations (Lotka 1920).

## Results and discussion

We have encoded the topology of PP interactions in a DNA-based molecular program. The information concerning the topology of the network is genetically stored in a 20-base-long ssDNA, G (for grass), which direct the growth of complementary preys (N) as follows: N hybridizes to the 3' end of G, to form the partial duplex G:N. This duplex is extended by a polymerase and subsequently nicked by a specific nicking enzyme yielding, upon de-hybridization, two copies of N and an intact template G.

**Figure 1:** Molecular predator-prey network. N, P and G denote the prey, the predator and the template respectively. Harpoon-ended arrows denote DNA strands. Double-sided arrows correspond to DNA hybridization/dehybridization reactions, whereas single-sided arrows indicate irreversible enzymatic transformations. Complementary DNA domains have the same colour. Strands have different hues, light and dark, indicating if they can or cannot be degraded by the exonuclease, respectively. Pol, nick and exo stand for bst DNA polymerase, Nb.BsmI nicking enzyme and ttRecJ exonuclease.

**Figure 2:** Waves of prey (yellow) and predators (green) in a 2D predator-prey molecular experiment. Left: Time-lapse images of the fluorescent shift in the corresponding fluorescent channels, taken every 10 min in a circular reactor 11 mm in diameter and 200  $\mu\text{m}$  thick. The borders of the reactor are highlighted in white. Middle: profiles along  $x$  of the yellow (prey) and green (predator) fluorescent shifts. Right: 1D reaction-diffusion simulations of the normalized prey and predator concentrations.

Predator P is a 14 bases long palindromic ssDNA. During predation N hybridizes over P and the polymerase extends this adduct to form a double strand P:P. Upon de-hybridization, P:P yields two copies of P. Both active species N and P are degraded to unreactive dNMPs by a 5'→3', processive, ssDNA-specific exonuclease. G is not digested because it bears three protective phosphorothioate modifications in 5'.

We have then confirmed the accuracy of our experimental model by observing sustained chemical cycles in a test tube maintained at a constant temperature. The period is from one to several hours and the oscillations of the two species can be monitored in two fluorescent channels. Tens of cycles can be obtained even in the absence of any exchange of matter. This demonstrates the transposition of an agent-based non-trivial network (and its dynamic behavior) at the molecular scale.

We have further extended the approach by adding additional ecologically-relevant interactions into the molecular ecosystem: competition for shared molecular resources, such as enzymatic catalysts can lead to complex, possibly chaotic behaviors, while symbiosis at the prey level tend to stabilize the steady coexistence of the species (Fujii & Rondelez 2013). We have also integrated a spatial component into the system by moving from well-mixed to reaction-diffusion systems. This has allowed the first observation of synthetic predator-

prey “waves of pursuit and evasion” (Murray 2004) under the microscope (Padirac et al. 2013).

## Abstract

We investigate the role of backward reactions in a stochastic model of catalytic reaction network, with specific regard to the influence on the emergence of autocatalytic sets (ACSs), which are supposed to be one of the pre-requisites in the transition between non-living to living matter.

In particular, we analyse the impact that a variation in the kinetic rates of forward and backward reactions may have on the overall dynamics.

Significant effects are indeed observed, provided that the intensity of backward reactions is sufficiently high. In spite of an invariant activity of the system in terms of production of new species, as backward reactions are intensified, the emergence of ACSs becomes more likely and an increase in their number, as well as in the proportion of species belonging to them, is observed. Furthermore, ACSs appear to be more robust to fluctuations than in the usual settings with no backward reaction.

This outcome may rely not only on the higher average connectivity of the reaction graph, but also on the distinguishing property of backward reactions of recreating the substrates of the corresponding forward reactions.

## Introduction

Models of catalytic reaction networks have been widely investigated in the last decades, with different goals and purposes, yet mostly in regard to the broad theme of the origin of life and with the design of artificial *protocells* (Carletti et al., 2008; Filisetti et al., 2010; Rasmussen et al., 2004; Serra et al., 2007; Szostak et al., 2001).

In particular, in the quest for a reasonable theory describing the transition from non-living to living matter, many frameworks have been proposed, among others the *metabolic-first* scenario (Dyson, 1985; Smith and Morowitz, 2004; Wächtershäuser, 1990; de Duve, 1982), the *protein-first* hypothesis (Oparin, 1924; Fox, 1974; Lee et al., 1996, 1997; Issac and Chmielewski, 2002), the *compartmentalization* (Bachmann et al., 1992), the *compositional* approach (Segré et al., 1999; Segre et al., 1998; Segré and Lancet, 2000) and the *gene-first* hypothesis included in the RNA world theory (Gilbert, 1986; Müller, 2006; De Luca et al., 2007; Anastasi et al., 2007; Talini et al.,

2009; Rios and Tor, 2009; Budin and Szostak, 2010). Even if the dispute is far from being concluded (Cornish-Bowden and Cárdenas, 2008; Stano and Luisi, 2010; Schrum et al., 2010; Budin and Szostak, 2010), one of the underlying key requirements in most of these theories is that the production of the molecular species involved in the transition relies on robust reaction pathways.

In this regard, some theories account for linear chemical pathways capable of producing the sufficient amount of species at energy-rich sites, e.g. hydrothermal vents (Ogasawara et al., 2000) or under plausible prebiotic conditions (Costanzo et al., 2009). Nevertheless, in most of the cases the emergence of sets of collectively self-replicating molecules, i.e. autocatalytic cycles (or *autocatalytic sets*, ACSs from now on)<sup>1</sup> appears to be an essential requirement to achieve the self-sustenance and the evolvability of the system. Indeed, there are many examples of ACSs in current biological systems, which are the outcome of billions of years of evolution. Therefore, the investigation of the generic properties of catalytic reaction networks, with particular respect to the sufficient conditions for the emergence of ACSs and the characterisation of their dynamical properties, is fundamental<sup>2</sup>.

<sup>1</sup>A classical definition of ACS is that of a subset of chemicals in which the production of each element is catalysed by at least another elements belonging to the subset (Kauffman, 1986). Hereinafter, a more formal definition with specific regard to our model will be provided.

<sup>2</sup>It is very important to remark that the presence of ACSs only is not sufficient to define *life*, which it is largely believed to require also the presence of a container that separates the living system from the environment, as well as a coupling between the replication rate of the internal molecules and the growth and division rate of the container. This theme is at the centre of the research on protocells.

In previous works (Serra et al., 2007; Filisetti et al., 2008; Carletti et al., 2008) we proved that, once that such a coupling is achieved, the rates of the replication of the internal molecules and that of the growth of the container tend to spontaneously synchronise through successive divisions. This also leads to an exponential growth of the population of protocells that, in turns, implies a Darwinian selection process among them (Munteanu et al., 2006).

Furthermore, in Serra et al. (2013) we introduced the first known

To this end, different models have been proposed by, e.g., Dyson (Dyson, 1985), Eigen and Schuster (Eigen and Schuster, 1977; Eigen and McCaskill, 1988; Eigen and Schuster, 1978), Kauffman (Kauffman, 1986; Hordijk et al., 2010; Hordijk and Steel, 2004; Mossel and Steel, 2005), Jain and Khrihna (Jain and Krishna, 1998), Lancet (Segre et al., 1998; Segré and Lancet, 2000), Kaneko (Kaneko, 2006) and Vasas and Fernando (Vasas et al., 2012). Despite the theoretical differences, most of the models predict a phase transition leading to the spontaneous emergences of ACSs, after matching certain key conditions, either structural or dynamical according to the cases. Note that, given that the presence of ACSs may eventually lead the system to display remarkable discrepancies between the concentration of the involved molecules from that of analogous systems with no ACSs, this could be actually investigated through wet-lab experiments.

Nonetheless, it is indeed difficult to detect the emergence of ACSs in lab experiments and this could be due, on the one hand, to the somehow drastic simplifications at the basis of the theoretical models or, on the other hand, to the fact that real experiments never matched the requirements suggested by the theories.

In order to fill the gap between theories and experiments and provide insights for further experimentation, in Filisetti et al. (2011c) we introduced a novel model of catalytic reaction network, based on a fully stochastic framework and in which the system complexity can grow according to the dynamics, through the creation of new species and reactions. The model takes inspiration from the works by Kauffman (Kauffman, 1986) and its subsequent developments by others (Bagley et al., 1989; Bagley and Farmer, 1992; Farmer and Kauffman, 1986; J.D.Farmer et al., 1986).

The model considers abstracted entities accounting for monomers and polymers (i.e. *species*) and simplified interactions among them, in terms of cleavages (i.e. the cutting of two species) and condensations (i.e. the concatenation of two species). The key constraint of the model is that each reaction must be catalysed in order to occur. In this regard, any species in the system can be selected to be the catalyst of any possible reaction with a certain probability. The system's dynamics is then stochastically simulated within an open flow reactor. By using a stochastic framework, it is possible to consider in an adequate way the relevance of noise, random fluctuations and low-numbers-effects on the overall dynamics, most of all when dealing with systems

---

stochastic model in which a catalytic reaction network is modelled within a simplified model of protocell. Although a stochastic description has been adopted also in Mavelli and Ruiz-Mirazo (2013), our model of protocell deals with the capability to create new molecular species by means of the reactions present in the system.

close to the phase transition in which the emergence of ACSs becomes plausible.

We remark that the focus of the model is *not* on the detailed characterisation of the entities and reactions of a specific chemical system, but rather on the investigation of the dynamical behaviour that emerges from the interaction of simple entities, with the final goal of deciphering the generic (or universal) properties, that is, those that are shared by a possibly broad range of different chemical systems. In particular, we aim at determining the minimal conditions for the emergence of ACSs and the sensitivity of the phenomenon to variations in some key parameters.

In this regard, in our previous works we studied in depth the influence that variations in some of the key parameters of the system has on the overall dynamical behaviour and on the production of ACSs.

One first result we obtained was to detect that a variation in the composition of the set of molecules present at the beginning of the simulation does not seem to remarkably affect the dynamics of the systems, whereas modifications in the incoming flux seem to deeply influence the overall behaviour (Filisetti et al., 2011c).

For this reason, we focused our attention on the incoming flux composition and diversity (Filisetti et al., 2011a). The results of the analysis that we performed showed that the a variation in the number of distinct species belonging to the incoming flux influences the general activity of the system: considering a fixed overall incoming flux concentration, the larger the number of diverse species (regardless their lower individual concentration), the higher the activity of the system, in terms of overall number of species and molecules, yielding a larger number of ACSs. On the contrary, the length of the polymers belonging to the flux seems not to be so relevant.

Another key parameter of the system, the average residence time of the molecules within the reactor, was also analysed, suggesting that the larger the residence time is, the higher the probability of emergence of ACSs is.

In another work, presented at *ECAL 2011* (Filisetti et al., 2011b), we introduced some plausible energy constraints associated to specific types of reactions, to investigate whether and how the introduction of a form of energy could affect the dynamics and the emergence of ACSs. Preliminary analyses showed that there exists an optimal combination of two key parameters, i.e. the incoming flux of energy carriers and the energization kinetic constant (which account for the amount of energy available for endoergonic reactions) and that this combination ensures a larger production of new species. Further research is needed for a better understanding of the phenomenon.

Finally, one of the most important results was to highlight the general fragility of the ACSs that have been observed. In fact, their existence usually depends on same rare molecules

and reactions, which may disappear because of random fluctuations, hence preventing the autocatalytic closure over a significant span of time. This outcome could provide one of the first possible explanations of the difficulty in observing the emergence of ACSs in wet-lab experiments.

In line with this methodological approach, within this work we carry on with the analysis of the key parameters of the system, in order to provide a more complete and coherent picture of the phenomenon.

In particular, we here relax one of the constraints of the classical formulation of the model, that is, the exclusion of backward reactions. In previous studies backward reactions were neglected, by hypothesising that the Gibbs energy  $\Delta G$  for any reaction is large enough to maintain the system far from the chemical equilibrium. Considering that backward reactions *do* occur in nature, here we want to investigate their role in the overall dynamics.

We define a cleavage (respectively, a condensation) as the *backward reaction* of a specific condensation (respectively, cleavage), i.e. the *forward reaction*, if:

- its products are the substrates of that condensation (respectively, cleavage),
- its substrates are the products of that condensation (respectively, cleavage).

The analysis has then been focused on the effects of the relative strength of the rates of the forward and the backward reactions.

In section II the model will be briefly outlined. In section III results of the simulations with backward reactions will be shown. Finally, in section IV the discussion and some indications for future works will be presented.

## The model

A detailed description of the model can be found in (Filisetti et al., 2011a,c), here we will only outline the key features. The model represents an open system in which monomer and polymers, i.e. the *species*, are involved in catalysed reactions. Every species  $x_i, i = 1, 2, \dots, N$  is defined by an ordered string of letters selected from an arbitrary alphabet (e.g. A, B, C...) and its amount, either concentration or quantity, i.e. number of *molecules*. The only allowed reaction types are: i) *cleavage*, the splitting of two species (e.g.  $AAAB \rightarrow A + AAB$ ) and the ii) *condensation*, i.e. the concatenation of two species (e.g.  $BBA + BA \rightarrow BBABA$ ), which requires an intermediate step involving the formation of a temporary complex between the substrate and the catalyst.

We neglect spontaneous reactions by assuming that there is a sufficiently high activation energy for any reaction scheme. Therefore, only catalysed reactions are allowed and every

species  $x_i$  (longer than a specific threshold) can be selected to be the catalyst of a given reaction with a certain (uniform) probability  $p_i = p, i = 1, 2, \dots, N$ . Therefore, the reaction scheme is defined in a probabilistic way, i.e. in different simulations the same species can be the catalyst of distinct reactions. Besides, the initial reaction scheme can dynamically evolve and increase in dimension because of the creation of new species, which can be (probabilistically) involved in either novel reactions as substrates, products or catalysts, provided that the coherence with the existent reaction scheme is maintained. The set of couples  $\{\textit{species}, \textit{reaction}\}$  in which the species catalyses the reaction defines the *chemistry* of the system, because it describes a coherent possible artificial world. Hence, it is possible to simulate distinct chemistries or to keep the chemistry fixed and simulate different time histories.

In the classical formulation of the model, backward reactions are also excluded, by hypothesising that the Gibbs energy  $\Delta G$  for any reaction is large. The main goal of this work is to investigate the implications of relaxing this constraint.

A possible example of each reaction type is shown:

- Cleavage:  $AB + C \xrightarrow{K_{cleav}} A + B + C$
- Condensation: (whole reaction:  $A + B + C \rightarrow AB + C$ )

A and B are two random species standing for the substrates of the specific reaction, C is the catalyst of that reaction and  $A : C$  is the transient complex.  $K_{cleav}$ ,  $K_{comp}$ ,  $K_{diss}$  and  $K_{cond}$  respectively are the kinetic rates of cleavage, complex formation, complex dissociation and final condensation<sup>3</sup>. The outgoing flux is simulated by assigning a common decay time  $K_{out}$  to each species and complex. The incoming flux rate  $K_{in}$  is measured in moles per second and the average residence time is given by  $1/K_{out}$ .

The dynamics of the system is simulated through the well-known Gillespie algorithm (Gillespie, 1977) for the stochastic simulation of chemical reaction system, with the key modification of allowing the creation of new species and reactions that are not present in the initial conditions. In particular, the system is modelled within a *continuous stirred-tank reactor* (CSTR), which allows continuous

<sup>3</sup>Notice that a parameter sensitivity analysis of the model was presented in Damiani et al. (2013). The main goal was to identify those kinetic parameters that mainly influence the ability of the system to increase the diversity of the species.

ingoing and outgoing fluxes of molecules. In another work (Serra et al., 2013) we introduced a semi-permeable membrane to separate the catalytic reaction network from the environment.

Two possible representations of the system are possible, which results in different graphs. The first concerns the catalytic activity of the system: an edge from  $x_c$  to  $x_i$  is drawn if species  $x_c$  is the catalyst of the reaction in which the species  $x_i$  is one of the products. This leads to the so-called *catalyst-product* graph. The second representation regards the assembling activity: an edge from  $x_j$  to  $x_i$  is drawn when  $x_j$  is a substrate involved in a reaction in which  $x_i$  is one of the products. This allows to draw the *substrate-product* graph.

Besides, the adoption of an asynchronous stochastic framework implies the problem of detecting cycles in a univocal way. We lastly decided to introduce a graph in which every edge (either catalyst-product or product-substrate) is maintained only if the specific reaction occurs within an arbitrary temporal window,  $W$ . We call it the *actual reaction graph* and can be applied to both the catalyst-product and the substrate-product graphs. In this way, the influence of very rare reactions is neglected and cycles can be coherently detected.

In particular, in the context of our model, we define as ACS a subset of species which belong to a *strongly connected component* (SCC) in the catalyst-product actual reaction graph<sup>4</sup>.

**The introduction of backward reactions.** The goal of this work is to investigate whether and how the introduction of backward reactions may influence the overall dynamics of the system and, in particular, with respect to the emergence of ACSs.

To this end, we define a backward reaction for any existing reaction of the system (which will be defined as forward reaction), relative to both cleavages and condensations (see the definition of forward and backward reactions in the previous section). In the example scheme above, the condensation is the backward reaction of the cleavage (or the other way round).

The analysis is then focused on the variation of a key parameter  $R$ , which accounts for the relationship between the forward and the backward reactions kinetic rates, and is defined as follows. Note that, given that in the current configuration of the system we set  $K_{comp} = K_{cond}$  for all the condensations, only  $K_{cond}$  will be included in the definition.

We distinguish two cases:

- if the forward reaction is a cleavage, given any  $K_{cleav}$ :

$$R = \frac{2K_{cleav}}{K_{cond}} \rightarrow K_{cond} = \frac{2K_{cleav}}{R} \quad (1)$$

- if the forward reaction is a condensation, given any  $K_{cond}$ :

$$R = \frac{K_{cond}}{2K_{cleav}} \rightarrow K_{cleav} = \frac{K_{cond}}{2R} \quad (2)$$

Varying  $R$  it is possible to define different ratios between the rates of forward and backward reactions and, accordingly, given the kinetic rates of any forward reaction to determine those of the corresponding backward reaction<sup>5</sup>.

## The simulations

The benchmark for this kind of analysis is the case in which no backward reactions are considered and that will be indicated with *NOREV* from now on. We then considered 4 values of  $R = 1, 10, 100, 1000$ .

We created 10 different chemistries and for each of them we varied the value of  $R$  only (simulating 10 different histories, for a total of 500 distinct simulations), in order to disentangle the effect of its variation on the dynamics. The details of the simulations can be found in the caption of Fig. 1.

In Fig. 1 we display the (average) number of distinct species present in at least one copy in time. No remarkable differences are detectable in the number of different species, which reaches an asymptotic value around 60 after a transient whose length is around 300 seconds, in all the cases. Notice that the number of distinct species (which somehow accounts for the *diversity* of the system) does not depend on the flux dynamics only, but on the general capability of the system of generating new species and reactions. Hence, this outcome suggests that the overall activity of the system, in terms of production of new species, is not enhanced by the introduction of backward reactions.

Moreover, a relatively moderate variation is observed also with regard to the asymptotic total number of molecules in the system, which is around 30.000 for all the distinct cases (not shown here).

The (average) number of molecules and that of species belonging to ACSs are shown in Fig. 2. We here have a indeed remarkable result: in correspondence of the lowest values of  $R$  (i.e. proportionally faster backward reactions) we observe a clear increase of the percentage of both molecules and species belonging to ACS, starting from the

<sup>4</sup>See the footnote number 1 at page 1 for a more general definition

<sup>5</sup>Notice that the factor 2 in Eq. 1 and 2 was chosen, in accordance with our previous works (Fuchslin et al., 2010), to roughly balance the speed of the cleavage, which is a one-step reaction, with that of the condensation, which is a 2-steps reaction.

Figure 1: Variation of the average number of species present in the system in time. The five lines represent the case with no backward reactions (*NOREV*) and those of systems characterised by values of  $R = 1, 10, 100$  and  $1000$ . The x axis represents time (in seconds). The values are averaged over 100 different simulations for each value of  $R$ . The bars represent the standard error.

The settings of the simulations are the following.

Alphabet: [A,B]; probability of catalysis,  $p$ : 0.00097; volume of the reactor:  $1e^{-18}L$ ; overall concentration =  $1e^{-4}M$ ; set of species in the influx: all the species up to length 4; minimum polymer length to have catalytic activity: 2; baseline  $K_{cond} = 50M^{-1}sec^{-1}$ , baseline  $K_{comp} = 50M^{-1}sec^{-1}$ , baseline  $K_{cleav} = 25M^{-1}sec^{-1}$ , baseline  $K_{diss} = 1e^{-6}sec^{-1}$ ; influx rate =  $1e^{-21}mol/sec$ ; simulation time: 1000 sec. 10 different chemistries are created, for each chemistry 5 different systems are created: with no backward reactions, with  $R = 1, 10, 100$  and  $1000$ ; for each system 10 different histories are simulated. The number of simulations is so 500.

benchmark case of no backward reactions, in which less than 5% of the molecules and of the species belong to ACSs (and analogously for slower backward reactions, i.e.  $R = 100$  and  $1000$ ), then the case of  $R = 10$ , in which around 20% of the molecules and of the species are in ACSs and up to case in which  $R = 1$ , which involves around 40% of the molecules and 45% of the species in the ACS dynamics. This result hints at a very important consideration: the faster the backward reactions are<sup>6</sup>, the more likely the emergence of ACSs with a large number of molecules and species is. It is even possible to hypothesise a threshold in  $R$  after which the emergence of large ACS becomes very likely, which would be, in this case, between  $R = 10$  and  $R = 100$ .

<sup>6</sup>Meaning proportionally faster with respect to forward reactions.

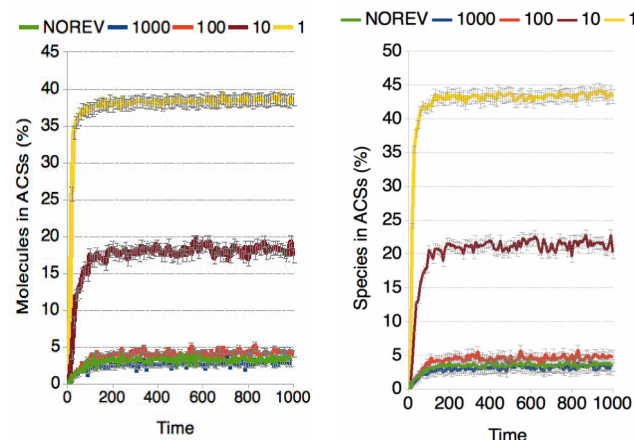

Figure 2: Variation of the average percentage of molecules (left) and species (right) belonging to ACSs in time, with respect to the cases: *NOREV*,  $R = 1, 10, 100$  and  $1000$ . The x axis represents time (in second). The bars display the standard error. The percentage is computed by looking at the molecules and species present at any time step in the system.

In Fig. 3 we report the variation of the number of ACSs (left) and that of percentage of species belonging to ACSs (right) in time, with respect to all the different simulations. Each row of the graph represents a distinct simulation, so it is possible to follow the dynamical evolution of any simulated system, with regard to these two key variables. By looking at the left graphs, regarding the number of ACSs in time, one first important result proves what stated above by analysing the average values. In correspondence of lower values of  $R$  a larger number of simulations is characterised by: i) the emergence of at least one (usually robust in time) ACS, ii) a larger number of distinct ACSs. Whereas for systems with no or very slow backward reactions (e.g.  $R = 1000$ ) in many case no ACSs emerge, when ACSs emerge are often not persistent in time (showing an oscillatory fashion) and the maximum number of observed ACSs is around 4, for low values of  $R$  ( $R = 1$  or  $R = 10$ ) in almost all the simulations at least one ACS is observed and we even observe simulations which yield a indeed large number of ACSs (up to 10 for  $R = 1$ ).  $R = 100$  seems to characterise an intermediate condition, perhaps close to a phase transition in which the emergence of ACSs becomes indeed likely.

Besides, given that the simulations are ordered in sets of 10 different histories for each one of the 10 chemistries, it is possible to notice how some chemistries are actually more efficient in producing ACSs, by looking at the large clearer stripes (i.e. 10 rows, corresponding to 10 histories of the same chemistry), e.g. for  $R = 10$  or  $R = 1$ .

In the right panels it is possible to observe the percentage of species belonging to ACSs in every simulation. For the cases in which only one or a few ACSs emerge (no

backward reactions or high  $R$ ) the fraction of species belonging to ACSs seems to show a strong correlation with the number of ACSs itself. Nevertheless, in the cases in which a larger number of ACSs emerge (low values of  $R$ ) we notice that this correlation is not always preserved and there are, on the one hand, simulations in which a very large percentage of species belong to a relatively low number of (big) ACSs and, on the other hand, others in which a large number of (small) ACSs involve a relatively low proportion of the species. This outcome would suggest that systems with relatively faster backward reactions display more heterogeneous dynamical behaviours.

It is also important to remark that while in the case with no or slow backward reaction at most 20/25% of the species are involved in the ACS dynamics, for low values of  $R$  this percentage increases dramatically, up to more than 70% for some simulation with  $R = 1$ , in which the dynamics of the system is monopolised by ACSs.

In Fig. 4 we show the percentage of molecules in ACSs at the end of the simulation (i.e. time = 1000) as a function of the average connectivity of the catalyst-product actual reaction graph (at time 1000) for all the different cases.

One can first notice that the systems with lower  $R$  correspond to higher average connectivities. This is a somehow expected result, given that the introduction of backward reactions implies an increase in the number of possible reactions and also that the lower the value of  $R$  is, the higher the probability of occurrence of these reactions is, resulting in a actual reaction graph which is increasingly more connected.

Besides, by looking at the line that interpolates the dots relative to the distinct cases (from the case of no backward reaction to the case of  $R = 1$ ), one can detect an apparently super-linear trend, which may underly some non-linear phenomenon, possibly related to the intrinsic nature of backward reactions. In fact, we here remark that the introduction of backward reactions does not simply imply a larger average connectivity for the system, as one of the features of backward reactions is to continuously recreate (as products) the substrates of the corresponding forward reactions. In particular, this action ensures the maintenance of the chains of reactions that guarantee the continuous flow of materials from the system's input toward the ACS structures. It is unlikely that the same reinforcement action of the ACSs' sustaining chains is provided simply because of the doubling of the number of reactions. In order to avoid the collapse, in fact, each ACS has to exactly guarantee the presence of the materials it is consuming: randomly created reactions have scarce chances to reinforce all the needed chemical species, whereas backwards reactions are automatically pointing toward the correct substrates. Given the autocatalytic nature of the ACS, this action is supposed

to guarantee the presence of the needed catalysts<sup>7</sup>.

Therefore, even though further analyses are needed to address this issue, we may suppose that this phenomenon entails important implications on the dynamics and stability of ACSs and, accordingly, to the percentage of molecules belonging to them.

## Conclusions and further developments

In this work we investigated the role of backward reactions in a stochastic model of catalytic reaction network in an open reactor.

The introduction of backward reactions involves significant changes in the overall dynamics, with particular regard to the emergence of ACSs, provided that their speed (hence, frequency of occurrence) is sufficiently high, as established by the kinetic rates and, in particular, by the proportion between the kinetic rates of forward and backward reactions. In other words, the intensity of backward reactions is fundamental to observe remarkable differences in the overall dynamics.

In detail, despite an observed substantial invariance in the number of different species (i.e. the diversity of the system) produced by the dynamics, as long as the relative values of the rates for the forward and backward reaction are decreased (i.e. the intensity of backward reactions is increased), an always higher number of these species is involved in an always larger number of different ACSs, in an increasing number of different simulations.

Besides, when backward reactions gain intensity the ACSs appear to be also more robust to variations and oscillations in time. This could represent a very significant result, mostly in regard with the dynamical fragility of ACSs that was observed in our previous analyses of systems without backward reactions.

It is also possible to hypothesize the presence of a threshold above which the likelihood of emergence of resistant ACSs dramatically increases.

One partial explanation of this general outcome is that backward reactions indeed add new reactions to the chemistry, leading to an increase of the average connectivity of the reaction network, which has been considered one of the key variables in regard to the emergence of ACSs (Filisetti et al., 2011c; Farmer and Kauffman, 1986; Jain and Krishna, 1998).

Nonetheless, the key property of backward reactions of recreating the substrates of the relative forward reactions could be essential in influencing the process of emergence of ACSs, not only because of the increase of the number of possible reactions, but mostly because of their action of reinforcement in favor of the supply chains supporting the

<sup>7</sup>Notice that we are currently designing experiments in order to separate the effects of doubling the number of reactions from those deriving by simple enabling the backward reactions.

existence of ACS structures. Note that this reinforcement action is stronger when the values of the reactions' forward and backward kinetic constants are closer, a circumstance that may have deeply influenced the chemical composition of the first historically functioning ACS structures. Analyses underway are aimed at addressing this issue. Furthermore, the phenomenon of competition for the same catalyst between forward and backward reactions could be another interesting phenomenon to investigate.

In another work (Serra et al., 2013) we introduced a model of catalytic reaction network in protocell, by considering the simplest possible architecture, that is a semi-permeable membrane that selects the species that can enter or exit the protocell.

Among the various results it was shown that protocells display distinct asymptotic behaviours, according to different variables, a property that has never been observed in CSTRs.

Preliminary analyses on the introduction of backward reactions in the protocell model would suggest that even mildly intense backward reactions would lead the system toward a more homogeneous dynamical behaviour. Even if further investigations are ongoing, this outcome would suggest another interesting role of backward reactions in this kind of system, also hinting at possible differences in the hypothesised threshold on the proportion among the kinetic rates.

### Abstract

We present a simulation of a cardiopulmonary system. The simulation is used within a serious game to help for nurses education. It runs in real-time and can be easily modified to represent different illnesses. The system can adequately react when a nurse executes an unexpected action on the patient. The simulator uses a bottom-up design to model the cardiopulmonary system, using simple mathematical models and basic interactions to reproduce high-level and complex behaviors.

### Introduction

Simulation is a good way to learn and practice in a safe environment. The simulation provides useful feedback to help students and trainees to learn from their mistakes. However in healthcare, most of the simulations and simulators require actors or mannequins (Issenberg et al., 2001; Morgan et al., 2006) to practice on. Since these simulations are expensive to use and can not be installed everywhere, it is hard for a student to practice anywhere else than schools and hospitals. Furthermore, most of these existing simulations for nursing education require the supervision of a technician or the use of a lot of parameters, which are often difficult to handle for an inexperienced user. Virtual simulations for nurses' training already exist (Hansen, 2008; Zary et al., 2006). However, most of them lack realism or tools needed by a teacher to provide useful and complete simulation for nursing students. To solve these major inconveniences, we propose a serious computer game coupled with a simulator that relies on interactions of simple components to reproduce complex behaviors. The model of the virtual patient is simplified and based on biological and physiological behaviors. It only specifies atomic parts of the complex system and the basic interactions between them. From these interactions, the required complex behavior emerges and can be studied. This innovative approach will help nurses taking charge of poly-trauma patients at the hospital. Given the low frequency of certain clinical situations in critical care, the use of computer simulations to develop and maintain skills is very well-advised. This active and autonomous learning mode, exercised in a virtual world, will facilitate the transfer of skills

in real-life situations. In the context of a shortage of clinical placement for nursing students, the computer simulation becomes a valuable tool within the reach of educational and health institutions to improve healthcare quality and patient safety.

The human body is a very complex system. Reproducing a perfectly accurate simulation of the human body would require a huge amount of computational resources and a perfect understanding of the underlying physiological processes. This is therefore an uneasy task if not, an impossible one. However, there are many efforts made to construct standards (Coveney et al., 2011; Clapworthy et al., 2008) and common parts (Ellaway et al., 2008) that could be used for a unified model of the human body. More realistic approaches, based on mathematical models like HumMod (Hester et al., 2011), are also developed. The mathematical approach of HumMod contains many variables and use complex formulas that represent the final behavior of the entire system. These models are very precise and require a good understanding of the underlying physiological processes. Researches in physiology and bioengineering are currently conducted to find these mathematical representations. One of the underlying objective of the presented simulator is to reproduce high level behavior without explicitly defining all possible interactions in the system with high level formulas used by these more classical mathematical models.

Most of the models developed for human body simulation use physiological and physical approaches to obtain adequate simulation (Attinger and Anné, 1966; MacIntyre, 2004). Some of them are slow to compute results, mainly due to the complexity of the formulas they used. Since the simulations must execute in real-time within a game engine, these models can not be used. The proposed model relies on such physiological and physical concepts. However, instead of representing complex interactions and using time-consuming computations, the system only uses basic physics formulas for on localized components, making it faster to compute.

In this paper, we present the cardiopulmonary system de-

veloped for the serious game used during the training of nurses. The next section describes the simulator and each of its subsystems. The third section shows some results of the simulator and a discussion about the simulator is presented in the fourth section.

## Simulator description

Our current version of the simulator models the cardiovascular and the respiratory systems. Each system is modeled after its biological functions. The simulator runs in real-time and can thus be linked to a game engine in order to simulate an emergency room with an injured patient. Each of the modeled systems is a simplification of the reality but its behavior is consistent with the physiological response of its human counterpart.

The update process of the simulator relies on the game engine. The game engine updates the simulator periodically using a time step ( $\Delta t$ ). Each system is updated accordingly to that time step by the simulator. For each update of a system, all its sub-components are also updated using this time step.

## Body definition

The simulator relies on a XML file to describe the human body. The entire body description is decomposed into different systems, i.e. cardiovascular, respiratory, nervous, muscular, etc. This paper emphasizes only the description and the simulation of the cardiovascular and the respiratory system. Each system is viewed as a list of connectibles and a list of organs. Each connectible represents the media used for information transfer. Connectibles are grouped in subsets representing logical unit of information diffusion. For example, the blood vessels and how they connect to each other in the right arm will be specified as a subset for the cardiovascular system. In the cardiovascular system, the connectible are called blood vessels. In the respiratory system, they are airways and alveoli. Each connectible can be linked to other connectible to create a circuit. Each subset can also be linked to others, creating a more complex circuit for information diffusion. A connectible can be split into sections of equivalent volume. Each of these sections contain a part of the body fluid that moves into the connectible. For the circulatory system, it is a blood part. Each fluid part contains different metabolites (see the metabolites section for the definition). Fig. 1 illustrates the different compounds of a system for the circulatory system. The use of XML file to specify the different values used by the model have many advantages. Among others, it can be easily modified and it is simple to understand. Since the simulator is used for nursing education, the XML specification is also an easy mechanism to specify injuries to the patient and to create new scenario and cases to practice on.

Figure 1: Simplification of the circulatory system to illustrate its different compounds. Each main color represents different subsets of connectible. The outermost bold rectangles are blood vessels (connectible). Inner rectangles are sections. Blood part (red circle) can contains different metabolites (purple circle). Blood vessels are linked together.

## Circulatory system

One of the main system of a human body is the cardiovascular system. The blood flows through the body, diffuses nutrients to various organs and retrieves waste produced by cells. Most of the non-nervous signals of the body use the cardiovascular system to reach their area of action. In the simulator, a virtual bloodstream is used as a transporter and is composed of two circulation loops. The first one is the pulmonary loop. The blood flows from the right ventricle of the heart to the lungs and returns back into the left atrium. The second is the systemic loop. The blood flows from the left ventricle of the heart and returns back into the right atrium after passing through the different parts of the body. The blood flows in blood vessels, creating a delay between the emission of the signals (like hormones) and the start of the associated effect. At the beginning of the systemic circulation loop, the blood vessels, called arteries, divide into smaller vessels. They subdivide until reaching the capillaries bed, modeled as a large container of blood to simplify the simulation. In these capillaries, nutrients contained in the blood can diffuse to irrigated organs. The waste produced by the organs are diffused into the blood of the capillaries. The blood then continues its way back into other blood vessels, called veins. The veins merge together on their way back to the heart. These splitting and merging of blood vessels mix the content of the blood to ensure a better repartition of metabolites into all systems of the body. It is also mimicking very well the human circulatory system since blood vessels also split and merge in the same way. Fig. 2 shows the schematic view of the cardiovascular system.

Each blood vessel, as a connectible, is divided into sections containing different blood parts, each of them having some metabolites. When the simulator updates the cardio-

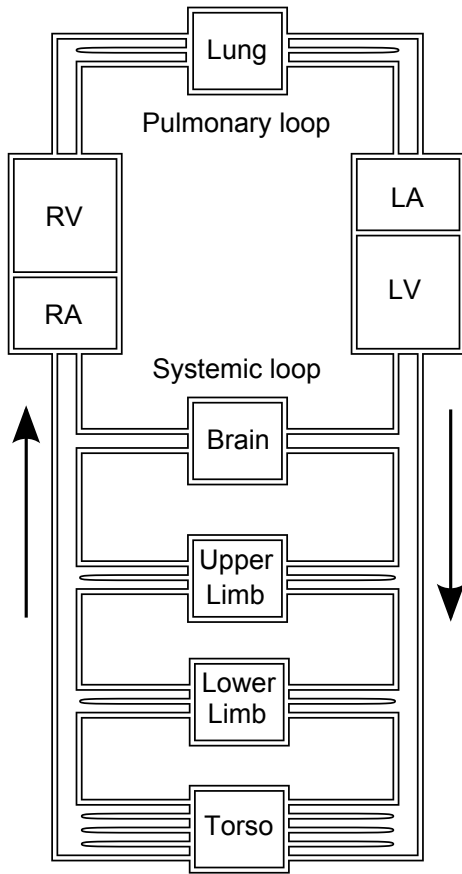

Figure 2: Schematic view of the cardiac model. LA and LV designate respectively Left Atrium and Left Ventricle. RA and RV designate respectively Right Atrium and Right Ventricle. The central boxes of the figure (i.e. Brain, Upper Limb, etc.) represent different connectible subset of the system. The subset contains arteries, veins and capillaries.

Figure 3: Schematic view of the update in blood vessels. The blood flows from left to right. In this example, each blood vessel contains five sections. Step 1 of the update process moves a certain quantity of blood from the last section of a vessel to the first section of all the next blood vessels, using Eq. 1. Then, step 2 to 5 move a certain volume of each other blood part to the next blood part in the vessel. This circulation of blood is executed in reverse order (from the last section to the first). It avoids transportation of new metabolites through all the blood parts of the blood vessels.

vascular system, each blood part flows through its vessel following the pressure gradient between that part and the next one in the vessel. In the simulation, each vessel is represented by a length ( $L$ ) and a radius ( $r$ ), thus modeled as a finite cylinder. This implies that each section of a blood vessel is also modeled as a cylinder of the same radius as the blood vessel but with a length of  $L/n$  for a vessel of  $n$  sections. To reproduce the pulsative flow of the blood, other simulations are based on the Windkessel effect, like Tsanas et al. (2009); Westerhof et al. (2009). The proposed simulator however relies on the standard Hagen-Poiseuille equation (Eq. 1) (Ganong et al., 2010; Marieb and Hoehn, 2010; Guyton and Hall, 2011) to calculate the volumetric flow rate ( $\phi_i$ ) in each blood vessel section  $i$  during a time step. The pulsatile work of the heart will impact the Eq. 1 by varying the pressure in a blood vessel section for a particular time step. The volumetric flow rate using the Hagen-Poiseuille equation is

$$\phi_i = \frac{\pi r_i^4 (P_i - P_{i+1})}{8\eta L_i} \quad (1)$$

where  $r_i$  and  $L_i$  are respectively the radius and the length of the  $i^{th}$  blood vessel section in which the blood flows.  $P_i$  and  $P_{i+1}$  are the pressure of the blood in these sections and  $\eta$  is the dynamic viscosity of the blood. The length of a blood vessel section remains constant through the simulation. The pulsatile flow produced by the heart must be damped. In the human body, the elasticity of the blood vessel is responsible for this damping. To mimic this behavior in the simulator, we propose a model inspired by Hook's law of elasticity. The difference in volume between the actual volume of the blood part and the relaxed volume of the blood vessel section replaces the displacement value in Hook's law. An adjusted elasticity constant ( $k$ ) is used, which can be specified for each blood vessel. The pressure  $P_i$  in the blood vessel section  $i$  is given by

$$P_i = \frac{k(V_i - W_i)}{2\pi r_i L_i} \quad (2)$$

where  $V_i$  is the volume of blood in the  $i^{th}$  vessel section and  $W_i$  is the relaxed (initial) volume of that blood vessel section. The resulting change in pressure at each time step influences the volumetric flow rate given by the Eq. 1 of the next time step.

During a time step ( $\Delta t$ ), all blood parts circulate throughout the sections of each blood vessel using the volumetric flow rate as explained previously. The new blood volume  $V'_i$  in each section  $i$  is represented with

$$V'_i = V_i - (\phi_i - \phi_{i-1})\Delta t \quad (3)$$

The blood part circulation is performed in reverse order. It is a design choice that required less memory than moving the blood parts in the way they flow. The simulator do not

have to keep an entire copy of each blood parts until the end of the update pass. The Fig. 3 shows the different steps to flow the blood through each sections of blood vessels. Each transferred blood part contains the same metabolites, in the same ratio, as the initial blood part they came from. Since volume changes at each time step, the blood flow is constantly recalculated.

As explained, the capillaries are modeled as a large container. In human body however, capillaries are large network of very small blood vessels. This arrangement of blood vessels induces a great resistance to blood flow due to the small radius of these vessels. The Eq. 1 can be rewrited as

$$\phi_i = \frac{(P_i - P_{i+1})}{R_i} \quad \text{with} \quad R_i = \frac{8\eta L_i}{\pi r_i^4} \quad (4)$$

where  $R$  is the resistance to blood flow of the blood vessel. In the simulator, since the capillaries are modeled as a large container, the resistance of the container must be adapted to represent more accurately the resistance of a network of blood vessels. Each capillaries container has a number of sub-vessels ( $n$ ). Each of them are identically modeled with a radius of 10 micrometers and a length proportional to the volume of blood of the entire capillaries container and the number of sub-vessel it contains. The model considers the sub-vessels in capillaries to be parallel, thus lowering the total resistance  $R_i$ , calculated with

$$\frac{1}{R_i} = \sum_{j=1}^n \frac{1}{R_j} \quad (5)$$

where  $R_j$  is the resistance in a sub vessel of the capillaries. Since all the  $R_j$  are identical, Eq. 5 can be simplified by

$$R_i = \frac{R_j}{n} \quad (6)$$

This model simplifies the blood flow in large and complex network of blood vessels in capillaries while keeping the physical incidence of their small radius on resistance.

To instill a pressure gradient to the bloodstream, the blood must be pumped. This role is devoted to the heart which is made of four parts. There are two atriums in which the blood arrives from the different circulation loops and there are two ventricles that pumped the blood out of the heart. The left atrium receives blood from the pulmonary loop while the right atrium receives it from the systemic loop. The simulated heart has also two group of self-polarizing cells, called sinoatrial node (SA node) and atrioventricular node (AV node). These nodes polarize and depolarize themselves to conduct the contraction of atriums and ventricles. For more details on heart nodes and their mechanisms, see (Guyton and Hall, 2011; Marieb and Hoehn, 2010). In the simulator, the polarization process goes through three different phases, as in reality. The first phase of the SA node is

the pacemaker. The pacemaker is a slow increase of the polarization of the node. The pacemaker phase is followed by a rapid depolarization until the maximum is reached. This abrupt depolarization emulates the sudden increase of ions (charged metabolites) that transfer through the membrane of the cells in a real heart. The contraction of the atriums happens at the end of that phase. Finally, the third phase is the repolarization until the minimum value is reached and the cycle restart. During the pacemaker phase, the atriums relax and retrieve their original volumes. The AV node follows the same process. However, when the SA node reaches its maximum polarization value, the node sends a signal to the AV node. That signal disturbs the pacemaker phase of the AV node and initializes the rapid polarization. The contraction of the ventricles occurs when the polarization of the AV node reaches its maximum value. The relaxation of the ventricle follows during the pacemaker phase of the AV node. This depolarization/polarization, which is only an exchange of charged metabolites (mainly of sodium and potassium) between the membrane of the cells forming the heart, is simplified for the simulator.

This level of details for the heart's implementation, using polarization levels, allows a better control over its reaction to external stimuli. Instead of using a predefined timer to conduct the heart's beat and trying to find the right value for it in the simulator, the hormonal and neuronal systems can increase or decrease the different value of polarization in the nodes to change the behavior of the heart allowing it to beat faster or slower.

## Respiratory system

The second simulated system is the respiratory system. This system is used to exchange the oxygen and the carbon dioxide between the body and the environment.

Like the human respiratory system, the virtual respiratory system has two main components, the lungs and the exterior environment. There are two lungs, and each of them is divided in different lobes. Each lobe contains alveoli in which the gases are exchanged with the blood in the capillaries. The lobes can be individually deactivated to simulate ill patients. The air enter the alveoli from the airways. The respiration control center is modeled as a timer. The rate of the respiration can be modified by changing the timer interval. It is in future plan to link this control center to a brain that will react to external stimuli, such as oxygen and carbon dioxide concentration as in real life. Fig. 4 shows the schematic of a lung in the system.

The air is modeled as an ideal gas (Eq. 7). And as a gas, it always fills all the available volume. The pressure  $P_{air}$  of the air depends on the volume  $V$  it fills, the temperature  $T$  in the lung, the quantity of gas ( $n$ ) and the ideal gas constant  $R$  with the relation

$$P_{air} = \frac{nRT}{V} \quad (7)$$

Figure 4: Schematic view of a simulated lung in the respiratory system. A lung is composed of lobes, each of them contains alveoli. The exterior environment is connected to the different alveoli using airways with one section. Capillaries of the circulatory system are linked to alveoli and exchange metabolites (i.e. oxygen and carbon dioxide) through gas diffusion.

The inspiration process increases the volume in the lung, while the expiration process decreases it. This difference of volume impacts the pressure of the air in the lungs, as explained by the Eq. 7. The air, as for the blood in the circulatory system, flows against its pressure gradient. But unlike the blood pressure, which depends of the elasticity of the blood vessels and the volume of blood it contains, the pressure of the air is calculated using the ideal gas equation (Eq. 7). In the simulator, the pressure of the exterior environment does not change as the respiration occurs. The air in the lung must always retrieve an equivalent pressure. Using Eq. 7, it is easy to find the amount of gas needed to balance the pressure between the lungs and the exterior environment. This amount of gas flows against the pressure gradient and balances the pressure in the lung at each time step.

The diffusion of gases between the blood and the alveoli of the lungs is driven by the partial pressure of these gases. However, each gas does not diffuse at the same rate. In the alveoli, all the gases composing the air are mixed together in a more complex gases mixture. This pressure of this mixture can be found using the Eq. 7. The partial pressure of each gas in the air can be calculated with the Dalton's law which states that the total pressure exerted by the mixture of non-reactive gases is equal to the sum of the partial pressures of each gases. For the air, the equation

$$p_i = P_{air} \frac{n_i}{n} \quad (8)$$

represents the partial pressure  $p_i$  of the  $i^{th}$  gas composing the air where  $n_i$  is the quantity in mole of this gas and  $n$  is the total amount of gases in the air. On the other hand, each gas dissolved in the blood has also a partial pressure. This partial pressure is calculated with the Henry's law stated as

$$q_i = \frac{n_i}{V} k_H \quad (9)$$

where  $q_i$  is the pressure of the  $i^{th}$  gas in the blood and  $n_i$  is the quantity of that gas in the blood.  $V$  is the volume of the blood part in which the gas is dissolved and  $k_H$  is the Henry's constant associated with the type of gas and the type of solution in which the gas is dissolved.

The diffusion of the gases takes place until the partial pressures in the air and in the blood are equal. Based on Fick's law of diffusion, the diffusion rate  $D_i$  of a gas  $i$  between the lung and the capillaries is

$$D_i = \frac{A(p_i - q_i)}{d} C_i \quad (10)$$

In this equation,  $C_i$  is the diffusion coefficient of the gas in the blood,  $A$  is the area of the blood vessel section that diffuses the gas,  $p_i$  and  $q_i$  are the partial pressure of that gas in the alveoli and in the capillaries and  $d$  is the distance of diffusion (Guyton and Hall, 2011). The quantity of gas  $Q_i$  added into the blood for a particular time  $\Delta t$  is

$$Q_i = D_i \Delta t \quad (11)$$

This diffusion process changes the respective partial pressure of oxygen in the blood and in the air of the alveoli. At the next time step, the diffusion rate changes accordingly and the cycle restarts upon equilibrium. For more information on gases diffusion in the human body, see Lumb (2010).

The respiratory system is responsible for the supply of new air into the body and for the expulsion of the exhausted one. In contrast with the circulatory system which is normally closed, the respiratory system is open. This particularity allows this system to be connected with different apparatus that provide breathable air or not. They are called the exterior environment. Normally, the respiratory system is connected to the atmosphere, composed at 78% of nitrogen and 21% of oxygen with the remaining being composed of many other compounds, like carbon dioxide and water vapor. The composition of this atmosphere influences the exchange of different gases in the lungs and in the body through the partial pressure of the composing gases. A higher concentration of oxygen in the air will increase the diffusion of this gas to the blood.

When the blood flows through the organs, it exchanges the oxygen and the carbon dioxide with them in a similar way than in the lungs. These exchanges change the partial pressure of these gases in the blood, resulting in continuous exchange when it passes through the lungs. The exchange

of gases in the organs follows the same principles as in the lungs with the equilibrium of partial pressures. The major difference is that the partial pressures of the gases in organs are found using the Henry's law (Eq. 9) instead of Dalton's law (Eq. 8). It is because the gases in organs are dissolved into the cells' fluids.

### Metabolites

All biological elements are called metabolites. Thus, every molecule that use the bloodstream or the pulmonary airways to circulate is considered to be a metabolite. It represents the oxygen, the carbon dioxide as well as the sodium, the potassium, the enzymes, the hormones and any other elements used by a system of the body. Like in human body, every blood parts, organs' fluid and air parts can contain metabolites. Instead of representing all the individual instance of a metabolite, like all atoms of oxygen dissolved in the blood, each metabolite is represented with a quantity representing the amount of individual instances. This simple representation of each set of metabolites in blood parts simplify the calculation in the different systems of the body. The pressure, the volume and the concentration, for example, can easily be found for a particular metabolite in a single blood part. The advantage of grouping all instances of the same metabolite limits the memory and the time needed to update all the systems. Furthermore, this simplification has only a small impact on the system, since it represents only a part of all instances of that metabolite in the whole body. The subdivision of the blood part and the air part allows precise control and limits actions to a specific section.

### Results

The developed system must be realistic enough to be used as a simulator for nurses education. The global behavior of the system must represents the way the human body behave in similar circumstances. The first experiment validates the behavior of the heart and the change in pressure into the bloodstream as the heart beats. It shows that cutting blood vessel to represent injuries has an impact on pressure. The second experiment validates the effect of the gases composing the atmosphere on the bloodstream. The experiment also demonstrates the effect of a ill lung to the respiratory system. The system needs 3 or 4 heart beats to stabilize at the beginning of a simulation.

### The Work of the Heart

The heart acts like a pump. It contracts and relaxes periodically. The effect of that pump is a continuous increase and decrease of the blood pressure in the arteries. The standard values of pressure for a healthy person are between 120 mmHg (or 16 000 Pascals) at the maximum and 60 mmHg (or 10 700 Pascals) at the minimum (Chobanian, 2004). These values represent the pressure in the blood vessels. It is the force exerted by the blood on a blood vessel wall. The

Figure 5: Pressure in the simulated aortic artery, at the exit of the heart. The pressure oscillates between 122 mmHg and 80 mmHg, which is in standard range for a main artery.

Figure 6: Blood pressure in a simulated artery that follows a cut. The green curve shows the volume of blood that has escaped through the cut. Red curve is the pressure in the artery when no cut is present in the system. Blue curve is the pressure in the same artery when a cut is present.

Fig. 5 shows the pressure of the blood in the simulated aortic artery at the exit of the left ventricle. The pressure rises when the heart contracts and decreases when the blood flows out of the heart.

To simulate an injured patient, the cardiovascular system allows blood vessels to be cut. The Fig 6 shows the effect of a cut at the end of the simulated artery network, before entering smaller capillaries vessels. Standard pressure in these arteries is lower since resistance and elasticity damped the pulse (Marieb and Hoehn, 2010). The volume of blood that leave the blood vessel is shown as well as the corresponding blood pressure in the next connected blood vessel. This cut to the artery should be deadly if no action is taken rapidly to mitigate the problem. The virtual patient rapidly loses blood, leading to a decrease in its pressure, and possibly death. The cut is considered open and the blood escap-

Figure 7: Blood volume variations of the left simulated ventricle over time. The first increase in blood represents the blood flowing from the left atrium to the left ventricle following the pressure gradient. The second increase occurs when the left atrium contracts, pushing the blood into the ventricle. The following decrease occurs when the ventricle contracts and expulses the blood into the aorta.

ing from the system exerts no pressure on the blood vessels or other organs. If the cut was modeled as a hemorrhage, the blood escaping the system would exert a pressure on the blood vessels, slowing the blood loss.

Another interesting feature of the simulator is the possibility to reproduce hypertension behavior. Results show that increasing the elasticity constant of a blood vessel, thus stiffening it, increases the maximum blood pressure in the neighboring vessels. Furthermore, the peak of the blood pressure in blood vessels occurs later in time with less elastic vessels, as explained in Mitchell (2006).

As explained previously, the heart is modeled as a pump with polarizations threshold. The pumping effect of the atriums and ventricles influences the volume of blood in the heart. The Fig. 7 shows the variations of the blood volume in the left ventricle of the simulated heart in relation with the polarization phases of the SA and AV nodes. The atriums contract when SA node reaches its maximum polarization value. The contraction of ventricles occurs shortly after when AV node reaches its own maximum polarization. The variation in blood volume for the ventricles is similar to the reality (Marieb and Hoehn, 2010).

### The Influence of the Air

Air composition influences the gas exchange in the human lungs. At the top of a mountain, the air pressure is lower than at sea level, which influences the partial pressure of oxygen. In the simulator, there is also a difference of partial pressure for the oxygen in the blood when the exterior atmospheric pressure changes. At sea level with standard atmospheric pressure (101 325 Pascals), the partial pressure of oxygen in the simulated blood is about 160 mmHg (104 mmHg in re-

ality) after passing the alveoli of the lungs. At 2000 meters of altitude (70 000 Pascals), the partial pressure of oxygen in the blood is about 110 mmHg (71.93 mmHg in reality) after passing the alveoli of the lungs. The difference of partial pressure of oxygen between the simulated blood and the reality is mainly due to the absence of water vapor in the air of the simulated lungs which increases the partial pressure of oxygen, following Eq. 8 (Marieb and Hoehn, 2010). The absence of water vapor simplifies the process of air exchange between the exterior environment and the simulated lungs. However, the results show clearly that a difference in initial atmospheric pressure impacts the system.

### Discussion

The goal of this work is to reproduce the behavior of a cardiopulmonary system. This simulator is used within a serious game for the training of nurses. One of the primary requirements of the system is a good representation of external and internal physiological processes. The system does not represent the exact reality. However, it must be realistic enough at a high level to create an immersive environment for the nurse. The presented simulator is based on simple mathematical concepts of chemistry and physics to mimic the basic interactions and behaviors of this complex system.

The presented approach, using a bottom-up design, relies on the principle of emergence to reproduce the complex interactions needed for this kind of simulation. This is in contrast with more standard approaches used in the video games industry. In a game, simulation and artificial intelligence often use finite-state machines. They are easy to define, the interaction between each component is clear and it can normally represent most of the desired behavior. However, relying on this model for a human body simulation has many disadvantages. First, there are many systems interacting together, thus complexifying the machine and increasing the chance to forget transitions when designing it. Second, this finite-state machine would required a huge amount of memory space and adding another system in the body simulation would require a lot of efforts to connect it with the others. Finally, every interactions on the model must be planned in the design stage, which are every actions and mistakes made by a nurse in training using the simulator. Naturally, predicting every mistakes and the order in which they will be made is a virtually impossible task. All these concerns have led us to create a simulator based on simple components interacting together so that complex behaviors can emerge.

The presented model is based on the subdivision of the entire system in logical units. The approach can be related to multi-agents system, where each part of the system executes its own job and send messages to other units to influence them. The model used for the simulator sends messages mainly through the bloodstream. An interesting effect of this message sending is the delay that occurs between the time a message is sent (i.e. an hormone is produced and re-

leased in the blood) and the time it reaches its zone of effect (i.e. when it binds to receptors to activate functions).

Again, the main advantage of using this kind of approach is the ability of the system to react automatically and adequately to the numerous possible actions of the nurses. When the simulator is in an unstable state, i.e. the virtual patient has injuries, the nurse in training must execute actions to stabilize it. When the nurse makes an action, the simulator must react adequately and it must continue running. The result of the action will impact the patient, thus reflecting what would happen in reality.

Mathematical models act in the same way as our approach. There is no need to plan every mistakes made by a nurse in the system. Actions will impact the formulas to provide new outputs. However, these models, even if they are extremely efficient and complete, can often be difficult to be divided and modeled as independent sub-system.

Modeling complex systems with simple components similar to multi-agents systems is an interesting idea that allows modularity, simplicity and speed of execution. The simpler formulas used in the presented simulator represent only basic physical interactions and are used to construct more complex behaviors. In a simulator that must reproduce global behavior instead of particular physiological principles, this modularity and simplicity of configuration offer a great advantage for both the developer of medical scenarios and the nurse in training.

## Conclusion

We describe a model of a cardiopulmonary system that is inspired by biological principles. The resulting behavior of the simulator corresponds to the actual behavior of a human body, thus allowing the simulator to be used for nurses' training. The decomposition into small and simple components to see the emergence of complex behaviors is an interesting way to model the problem. The teacher can specify injuries and illness to a patient, thus simplifying the creation of new medical scenarios.

## Acknowledgments

The research was supported in part by grants from the Mitacs Acceleration program. We also wish to thank the contribution of GolemLabs in the project, a video game company. Special thanks to all the GRITS (Research group in techno-pedagogy innovation in healthcare from University of Sherbrooke) members for their contribution to this work.

### Abstract

If a space-time with a causal relationship is viewed from an observer in space-time, the interaction between space-time and the observer has to be implemented. We describe this interaction using a pair of causal sets and its semantics or using a pair of Point and Open Logic. We here propose an artificial causal space-time called an evolutionary topological system, which is based on the changeability between logical operations (disjunction and conjunction) and logical elements (join and meet) of a causal set. The conflict resulting from the interaction is locally and temporally removed by replacing disjunction and join (or conjunction and meet), and a causal set is verified to evolve to a particular logical structure based on the simple summation. We also show this model can design an abnormal space-time feeling, such as an out-of-body experience.

### Introduction

One of the most intriguing and important models for subjective and/or cognitive time was proposed by a philosopher, McTaggart (1908). He evaluated two model types, called the A series and B series. The B series consists of events that are linearly ordered and designated by “before” and “after”. The A series consists of past, present and future events that cannot co-exist and are exclusive of each other. Although McTaggart himself argued that neither the A nor B series can be a model for time, the A and/or B series are still used as models for time in philosophy (Grey, 1997; Mellor, 1998; Gunji et al., 2009).

Although the original A and B series appear to be too speculative to be considered models for time, a pair of the A and B series can be utilized as a causal set (Bombelli et al., 1987) and its semantics in the field of quantum mechanics (Markopoulou, 2000), independent of philosophy. The B series corresponds to a causal set defined by a partially ordered set. The A series corresponds to a sieve in the semantics of a causal set. Thus, the idea of the A and B series is taken as a causal relationship and can be argued in quantum gravity (Klugry and Sepanina, 2011).

A causal set that serves as a model for causal relationships in space-time is a given for an observer. It is assumed that an observer living in a space-time passively observes, memorizes and recalls a series of events and calls that set of events the past, present or future, depending on the location of the observer. Although Markopoulou introduced the stance of an observer who observes a space-time internally, the

interaction between an observer and space-time was not described. The role of an observer still remains.

We here propose an artificial causal space-time in which an observer moving in a space-time can interact with space-time itself. Why does the interaction occur? Independent of the idea of a causal set, Vickers (1996) proposed the generalized idea of a causal set and its semantics in the form of a topological system. In this framework, logical operations are defined in a causal set, called Point Logic, and in its semantics, called Open Logic. Because a generalized causal set and its semantics are related to each other by a particular binary relationship, they are restricted with respect to each other. It entails a conflict between Point and Open Logic that has to be resolved, which is why the interaction between Point Logic (in a causal set) and Open Logic (in its semantics) can occur.

Against a conflict, Vickers introduced a limited logical operation that is found as ubiquitously as Scott topology (Scott, 1976). In other words, his solution to resolve a conflict results from the stance of an observer who sees a space-time externally. Once his solution is introduced, a conflict never occurs. Therefore, in principle, there is no interaction between an observer and space-time.

Our artificial causal space-time is a dynamic causal set equipped with a particular rule by which perpetually generated conflicts between a causal set and its semantics are discarded locally and temporally. Even if a local consistency is generated, removing the local conflict can generate another local conflict. This dynamic evolves a causal set toward a particular system in which the cause-effect relationship can be calculated by summing up the causes. We also show that the interaction of Point and Open logic can generate a particular subjective sensation called an “out-of-body experience (OBE)” that seems to differ from the OBE previously reported (Ehrsson, 2007; Lenggenhager et al., 2007). Our model suggests how to create new sensations and emotion in subjective space-time.

### Causal sets and Topological System

Imagine a series of events in time, such as  $\dots \rightarrow x_1 \rightarrow x_2 \rightarrow x_3 \rightarrow \dots$ , and you are at event  $x_2$ . The future and past of  $x_2$  can be expressed as the set of  $\{\dots, x_1, x_2\}$  and  $\{x_2, x_3, \dots\}$ , respectively, and the present at event  $x_2$  is expressed as the intersection of the future and past as  $\{x_2\}$ . This idea is the

essence of the B and A series presented by McTaggart (Gunji et al., 2010).

A causal set is a set of events defined as a partially ordered set. Its semantics is a collection of, for example, all possible futures. This pair can be a generalized pair of the B and A series. In addition, the introduction of the relationship between a causal set and its semantics derives motivation for the interaction between a causal set and its semantics.

### Causal set and its semantics

**Causal set and space-time.** A causal set consists of separable events. Each event can be connected to another event via a directed edge without loops. If two events are connected by two edges that have different directions, they are equivalent to each other. Thus, this particular directed network can be expressed as a partially ordered set (POS) (Davey and Priestley, 2002). If an event and a directed edge are expressed as an alphabet and  $\leq$ , respectively, the POS satisfies the following: (i)  $a \leq a$ , (ii)  $a \leq b$  and  $b \leq a$  implies  $a = b$ , and (iii)  $a \leq b$  and  $b \leq c$  implies  $a \leq c$ .

Figure 1. A causal set,  $P$ , and its semantics,  $\uparrow P$ . In a causal set, partial order,  $\leq$ , is expressed as an arrow. In  $\uparrow P$  an element of  $\uparrow P$  (i.e., a subset of  $P$ ) is expressed as a circle. If  $A \subseteq B$ , they are connected by a line with upper  $B$  and lower  $A$ . A filled circle represents  $\uparrow p$  with  $p$  in  $P$ .

Some terminologies are also added. Any elements  $a$  and  $b$  in a POS,  $P$ , are anti-chain with each other if neither  $a \leq b$  nor  $b \leq a$  holds. For any subsets,  $Q \subseteq P$  join of  $Q$ , denoted by  $\vee Q$ , is defined such that for any  $q \in Q$ ,  $q \leq \vee Q$  and if  $q \leq s$ , then  $\vee Q \leq s$ . In particular, if  $Q$  is a two-element set such as  $\{a, b\}$ ,  $\vee \{a, b\}$  is represented by  $a \vee b$ . Similarly, the meet of  $Q$ , denoted by  $\wedge Q$ , is defined such that for any  $q \in Q$ ,  $q \geq \wedge Q$  and if  $q \geq s$ , then  $\wedge Q \geq s$ . If  $Q$  is a two-element set such as  $\{a, b\}$ ,  $\wedge \{a, b\}$  is represented by  $a \wedge b$ . Given a partially ordered set,  $P$ , if for any  $x, y \in P$ ,  $x \wedge y, x \vee y \in P$ , then  $P$  is called a lattice.

Given a POS,  $P$ , for any  $p \in P$ , the future of  $P$  is defined by  $\uparrow p = \{x \in P \mid p \leq x\}$ . The semantics of  $P$  is a collection of the possible unions of all  $\uparrow p$  for any element  $p$  in  $P$ . Thus, it is defined by  $\uparrow P = \{\uparrow Q \mid Q \subseteq P\}$  where  $\uparrow Q = \{y \in P \mid (\exists x \in Q) y \geq x\}$ . Fig. 1 shows an example of a causal set,  $P$ , and  $\uparrow P$ .

In  $P$ , the future of  $b$  is expressed as  $\uparrow b = \{b, c, d, e\}$ . Similarly,  $\uparrow c = \{c, d\}$ , and then  $\uparrow c \subseteq \uparrow b$ . Any elements other than  $\uparrow p$  (with

$p$  in  $P$ ) in  $\uparrow P$  are expressed as a union of the  $\uparrow p$ 's (with  $p$  in  $P$ ), such as  $\{b, c, d, e, f, g\} = \uparrow b \cup \uparrow f$ . Tracing the filled circle in  $\uparrow P$ , one can see that the ordered structure of  $P$  is embedded in  $\uparrow P$ .

In the context of a causal set, there is no discussion about the relationship between a causal set and its semantics. The relationship is introduced in the context of formal logic, independent of the idea of a causal set. It is called a topological system.

**Topological system.** Given a set  $S$ , if a collection of subsets of  $S$  satisfies an axiom of opens, it is called a topology or topological space. An axiom of opens is the following: (i)  $S$  and empty set are opens, (ii) a finite intersection of opens is an open, and (iii) a union of opens is an open. A power set that is a collection of all subsets of  $S$  is the densest topology, and a collection consisting only of  $S$  and empty is the sparsest topology. Topology is a type of metric that can be used to recognize a set,  $S$ .

Because topology is constrained under a particular axiom of opens, Vickers (1996) attempted to generalize a topology in the form of a binary relationship between a collection of points and a collection of opens, which he called a topological system. A collection of points and opens is defined by a triplet,  $\langle P, L, R \rangle$ , where  $P$  is a set,  $L$  is a locale and  $R$  is a binary relationship between  $P$  and  $L$ . A locale is a partially ordered set that is closed with respect to union (disjunction),  $\cup$ , and finite intersection (conjunction),  $\cap$ , and that satisfies the distributive law, such that for any  $a, b$ , and  $c \in L$ ,  $a \cap (b \cup c) = (a \cap b) \cup (a \cap c)$ . It is trivially true that a triplet  $\langle P, \uparrow P, \in \rangle$  also satisfies the definition of a topological system.

Because a locale contains logical operations, we can define logical operations for opens. What about points? Imagine an observer moving in a causal set,  $P$ . He can manipulate logical operations for an element of  $\uparrow P$ , which is derived from a basic assumption in which an observer discriminates an event from other events and recognizes a set created from  $P$ . Thus, he can also manipulate a logical operation for events. It is, therefore, reasonable that a logical operation for points is also introduced.

### Point Logic and Open Logic

**Definition of Point and Open Logic.** Given a causal set, its semantics and the binary relationship between them, such as the triplet  $\langle P, L, R \rangle$ , Vickers (1996) introduced logical operations in both  $P$  and  $L$ . For  $S$ , a subset of a local, logical operation, conjunction (AND)  $\cap$  and disjunction (OR) are defined by

$$xR \cap S :\Leftrightarrow (\forall a \in S) xRa \quad (1)$$

$$xR \cup S :\Leftrightarrow (\exists a \in S) xRa \quad (2)$$

Because a locale is a generalization of an open set in topological space, logic in a locale is called Open Logic.

Similarly, for  $T$ , a subset of  $P$ , conjunction and disjunction are defined by

$$\cap Tra :\Leftrightarrow (\forall x \in T) xRa \quad (3)$$

$$\cup Tra :\Leftrightarrow (\exists x \in T) xRa \quad (4)$$

Because an element of a set is a point, logic in  $P$  is called Point Logic. These logical operations can also be defined in  $\langle P, \uparrow P, \in \rangle$  by using  $\in$  instead of  $R$ .

**Conflict between Point and Open Logic.** Although Point Logic is defined for a point and Open Logic is defined for a set, logical operations are defined in the same manner, and they are related by a binary relationship, which entails a conflict between Point and Open Logic. The question arises as to how we can resolve this conflict.

Let us consider a causal system,  $\langle P, \uparrow P, \in \rangle$ . Given a partially ordered set  $P$ , the followings two are trivially true:

$$a \cup b \in \{a\}, \quad a \cup b \in \{b\}. \quad (5)$$

Because the left-hand term means  $a$  or  $b$  even if the right-hand set contains either  $a$  or  $b$ , then the statement holds. Thus, statement (5) holds because of definition (4). Statement (5),  $a \cup b \in \{a\}$  and  $a \cup b \in \{b\}$ , means that  $a \cup b$  belongs to both  $\{a\}$  and  $\{b\}$ . In other words,  $(\forall a \in S) x \in a$  where  $x = a \cup b$  and  $S = \{\{a\}, \{b\}\}$ . Due to definition (1), we obtain

$$a \cup b \in \{a\} \cap \{b\}. \quad (6)$$

However, statement (6) also means that  $(a \in \{a\} \text{ and } a \in \{b\})$  or  $(b \in \{a\} \text{ and } b \in \{b\})$ ; this statement thus never holds. This type of statement results from the conflict between Point and Open Logic.

A solution proposed by Vickers is to restrict an operation of disjunction. In statement (6), disjunction is applied to a set  $\{a, b\}$ , which results in  $\cup\{a, b\} = a \cup b$  in the left-hand term. That result entails a conflict. In Vicker's solution, disjunction can be operated only to a directed set,  $D$ , which is defined by the following: for any  $x, y \in D$ , there exists  $z \in D$  such that  $x \leq z$  and  $y \leq z$ . Note that  $\{a, b\}$  is not a directed set because  $a$  and  $b$  are anti-chains for each other. Why are they anti-chains? If  $a \leq b$  or  $b \leq a$ , the right-hand set can be replaced by  $\{a, b\} \cap \{b\}$  in the case of  $a \leq b$ , or  $\{a\} \cap \{a, b\}$  in the case of  $b \leq a$ , because any sets in the right side of  $\in$  have to be an element of  $\uparrow P$ .

Because  $a \leq a \vee b$  and  $b \leq a \vee b$ ,  $\{a, b, a \vee b\}$  is a directed set. In considering the case in which a join  $a \vee b$  exists and  $\cup\{a, b, a \vee b\}$ , the right-hand term in (6) has to be replaced by  $\{a, a \vee b\} \cap \{b, a \vee b\}$ . Therefore, we obtain

$$a \cup b \cup a \vee b \in \{a, a \vee b\} \cap \{b, a \vee b\}. \quad (7)$$

Thus, at least one of  $a, b$  or  $a \vee b$  belongs to both  $\{a, a \vee b\}$  and  $\{b, a \vee b\}$ , which is why statement (7) holds. When disjunction is applied only to a directed set, this particular disjunction is called a directed disjunction and is represented by  $\cup^\uparrow$ . Thus, definition (4) in a causal system  $\langle P, \uparrow P, \in \rangle$  is replaced by

$$\cup^\uparrow T \in a : \Leftrightarrow (\exists x \in T) x \in a, \quad (8)$$

where  $T$  is a directed set. Inversely, conjunction in Point Logic related to disjunction in Open logic entails a conflict that can be resolved by directed disjunction in Open Logic.

This type of solution to resolve a conflict is the construction of a one-to-one correspondence between Point and Open Logic by discarding parts that cannot be correspondent with each other. Although one-to-one correspondence is achieved,

logical operations are restricted and used incompletely. Alternatively, we here intend to propose a solution to resolve the conflict in which logical operation is not restricted.

## Causal dynamics with local consistency

How can we resolve the conflict between Point and Open Logic? Instead of introducing directed disjunction, we here introduce the changeability of join and disjunction and of meet and conjunction. Actually, if we can replace disjunction with join in  $P$  whenever we use disjunction, the conflict between Point and Open logic can be resolved. For example, considering statement (6), one can obtain

$$a \vee b \in \{a, a \vee b\} \cap \{b, a \vee b\}. \quad (9)$$

Thus, by manipulating  $a$  and  $b$ , there exists a join of  $a$  and  $b$ , and  $a \cup b$  can be replaced by  $a \vee b$ . The conflict can be resolved by this changeability of disjunction and join and of conjunction and meet, which is why the changeability can be interpreted as a local consistency between Point and Open Logic.

The changeability of conjunction and meet can be verified, but that of disjunction and join cannot be proved. To create a causal system  $P$  that satisfies the changeability of disjunction and join,  $P$  is locally modified by a particular rule that is a local modification based on the dynamics of a causal system. First, we show the verification of the changeability.

### Changeability of logical operation and element in $P$

**Conjunction and meet.** Because each element of  $\uparrow P$  is expressed as an upper set of  $P$ , the changeability of conjunction and meet is expressed via  $\uparrow x$  with  $x \in P$ .

#### Proposition 1 (Changeability of conjunction and meet)

Given a topological system  $\langle P, \uparrow P, \in \rangle$ , for any  $a, b, x \in P$ ,  $a \cap b \in \uparrow x \Leftrightarrow a \wedge b \in \uparrow x$  if there exists  $a \wedge b$  for  $a$  and  $b$ .

**Proof.** (i) Assume  $a \cap b \in \uparrow x$ . It means that  $a \geq x$  and  $b \geq x$  and then  $x$  is a lower bound for  $\{a, b\}$ . Because of the meet, the greatest lower bound  $a \wedge b$  is larger than  $x$ ,  $a \wedge b \in \uparrow x$ . We verified  $a \cap b \in \uparrow x \Rightarrow a \wedge b \in \uparrow x$ .

(ii) Assume  $a \wedge b \in \uparrow x$ . We obtain  $a \wedge b \geq x$ . Because  $a \geq a \wedge b$  and  $b \geq a \wedge b$ , we obtain  $a \geq x$  and  $b \geq x$ , which means  $a \cap b \in \uparrow x$ .

#### Proposition 2 (Semi-changeability of disjunction and join)

Given a topological system  $\langle P, \uparrow P, \in \rangle$ , for any  $a, b, x \in P$ ,  $a \cup b \in \uparrow x \Rightarrow a \vee b \in \uparrow x$  if there exists  $a \vee b$  for  $a$  and  $b$ .

**Proof.** Assume  $a \cup b \in \uparrow x$ . It means that  $a \geq x$  or  $b \geq x$ . Because  $a \vee b \geq a$  and  $a \vee b \geq b$ ,  $a \vee b \geq x$  always holds. Thus, we obtain  $a \vee b \in \uparrow x$ .

The inverse of proposition 2, in which  $a \vee b \in \uparrow x \Rightarrow a \cup b \in \uparrow x$ , never holds. A counterexample is given by a partially ordered set,  $\{a, b, x, a \vee b\}$ , where  $a \vee b \geq x$  and  $a, b$  and  $x$  are anti-chain with each other. Although  $a \vee b \in \uparrow x$  holds in this partially ordered set,  $a \geq x$  or  $b \geq x$  never holds because they are anti-chains. Thus,  $a \vee b \in \uparrow x \Rightarrow a \cup b \in \uparrow x$  does not hold in

general. Therefore, the changeability of disjunction and join never holds in any partially ordered set.

Thus, we define a particular dynamic by which the changeability of disjoint and join is locally implemented.

## Dynamical system for local consistency

We implement a dynamic for the changeability of disjunction and join and simulate the time development of an evolutionary causal set. For this purpose, we define a causal set consisting of binary sequences.

**Definition 3 (Causal set of binary sequences)** A causal set,  $P$ , of binary sequences consists of  $n$  bits of sequence,  $\mathbf{a} = \langle a_1 a_2 \dots a_n \rangle$  where each  $a_k = 0$  or 1 for any  $k \in \{1, 2, \dots, n\}$ . The order is  $\mathbf{a} \leq \mathbf{b}$  if  $a_k \leq b_k$  for any  $k \in \{1, 2, \dots, n\}$ .

Figure 2. Some examples of a causal set of binary sequences. Each element represented by a binary column is expressed as a decimal number. If there is no join or meet, -1 is returned.

Fig. 2 shows three examples of a causal set of binary sequences. Only the right lower set is a lattice, and the others are not. A binary column represents a binary sequence, where the black and white squares represent 1 and 0 digits, respectively. A decimal number is representation of a binary sequence. Join and meet for a two-element set are shown as an example.

Notice that join is not a union of binary sequences and that meet is not intersection. Here, we denote a union by the symbol  $\oplus$ . For a pair of binary sequences,  $\mathbf{a}$  and  $\mathbf{b}$ ,  $\mathbf{a} \oplus \mathbf{b} = \langle \dots a_k + b_k \dots \rangle$  where  $0+0=0$ ,  $0+1=1+0=1+1=1$ . If a union  $\oplus$  is applied to  $\{1, 2\}$  in the causal set in the lower right of Fig. 2, we obtain  $1 \oplus 2 = 3$ . Because there is no binary sequence represented by 3 in this causal set, we obtain  $1 \vee 2 = 19$ . Similarly, meet is not an intersection. Here, we denote intersection by the symbol  $\otimes$ . For  $\mathbf{a}$ ,  $\mathbf{b}$ ,  $\mathbf{a} \otimes \mathbf{b} = \langle \dots a_k b_k \dots \rangle$  where  $0 \times 0 = 0 \times 1 = 1 \times 0 = 0$ ,  $1 \times 1 = 1$ . If an intersection is applied to  $\{11, 7\}$  in the upper right of Fig. 2,  $11 \otimes 7 = 3$  is obtained. However, because there is no 3, we then obtain  $11 \wedge 7 = -1$  (i.e., there is no meet).

Given a causal set of binary sequences, we introduce the dynamics of a causal set and define an evolutionary topological system.

**Definition 4 (Evolutionary topological system)** An evolutionary topological system is defined by  $\langle P^i, \uparrow P^i, \in, F \rangle$ , where  $P^0$  is an initial causal set of  $n$  bit sequences that are randomly given. The time development of a causal system is defined by

$$P^{t+1}=F(P^t) \quad (10)$$

where  $F(P^t)$  is defined by the following:

- (i) Randomly choose two elements  $\mathbf{a}$  and  $\mathbf{b}$  from  $P'$  and obtain  $\uparrow \mathbf{a}$  and  $\uparrow \mathbf{b}$  from  $\uparrow P'$ .
- (ii) If the statement  $\mathbf{a} \wedge \mathbf{b} \in \uparrow \mathbf{a} \cup \uparrow \mathbf{b}$  does not hold, then calculate  $\mathbf{a} \wedge \mathbf{b}$ .
- (iii) If  $\mathbf{a} \wedge \mathbf{b}$  does not exist, calculate  $\mathbf{a} \otimes \mathbf{b}$ , and then each bit with a 1 value is replaced by 0 or nothing happened with an equal probability. When this replacement is denoted by  $\text{RAND}_1$ , we add the new element of

$$a \wedge b = \langle \dots \text{RAND}_1(a_k \times b_k) \dots \rangle \quad (11)$$

- (iv) If the statement  $a \cup b \in \uparrow a \cap \uparrow b$  does not hold, then calculate  $a \vee b$ .
- (v) If  $a \vee b$  does not exist, calculate  $a \oplus b$ , and then each bit with a 0 value is replaced by 1 or nothing happened with an equal probability. When this replacement is denoted by  $\text{RAND}_0$ , we add the new element of

$$a \vee b = \langle \dots \text{RAND}_0(a_k + b_k) \dots \rangle \quad (12)$$

- ```

to  $P^j$ .
(vi) Choose  $c$  from  $P^j$ 
(vii) If  $(a \vee b \geq c)$  {
        if  $(a \geq c$  or  $b \geq c)$  {
        } else {
            if  $(c \wedge a$  and  $c \wedge b$  are anti-chain) {
            } else {
                Remove  $c$  from  $P^j$ 
                Add  $x$  such that  $a \geq x$ 
            }
        }
    }
}

```

The dynamics of an evolutionary topological system are based on the changeability of conjunction and meet and of disjunction and join. According to Proposition 1, if the meet of  $\mathbf{a}$  and  $\mathbf{b}$  exists, then it can be replaced by the conjunction of  $\mathbf{a}$  and  $\mathbf{b}$ . Thus, the meet of  $\mathbf{a}$  and  $\mathbf{b}$  is generated for the changeability of meet and conjunction. Notice that, due to  $\text{RAND}_1$ , a generated meet is not an intersection.

In contrast, given Proposition 2,  $a \vee b \in \uparrow x \Rightarrow a \cup b \in \uparrow x$  does not hold even if the join of  $a$  and  $b$  exists. As mentioned previously, in a causal set  $\{a, b, c, a \vee b\}$  where  $a \vee b \geq c$  and  $a, b$  and  $c$  are anti-chain with each other,  $a \vee b$  cannot be replaced by  $a \cup b$ . Thus, this type of case is removed. This procedure is implemented by “Remove  $c$  from  $P$ ”. However, in the case of  $P' = \{a \leq c \leq a \vee b, b\}$ , if  $c$  is removed and  $x$  is added such that  $x \leq a$ .

a causal set with the same structure,  $P^{t+1} = \{x \leq a \leq x \vee b, b\}$ , is obtained. Thus, this process has fallen into infinite regression. Actually, in a causal set of binary sequences with a finite length, this process turns a causal set degenerate into a one-point set of the least element,  $0$ , which is why the procedure (vii) discards the case of the subset,  $\{a \leq c \leq a \vee b, b\}$ , from removing the  $c$  procedure

Figure 3. Time development of an evolutionary topological system.  $P^1, P^2, \dots, P^5$  of 9-bit sequences are shown in the form of a Hasse diagram. All elements of  $P^t$  are represented by binary columns above  $P^t$ .

Figure 4. A causal set of an evolutionary topological system has evolved into a distributive lattice.

Fig. 3 shows the time development of an evolutionary topological system. Each causal set,  $P^t$ , is represented in the form of a Hasse diagram (i.e., if  $a \leq b$  and there is no other element between  $a$  and  $b$ ,  $a$  and  $b$  are connected by a line). The initial causal set is randomly given, and  $P^{t+1} = F(P^t)$  is iterated.

Various time developments suggest that the dynamics defined in definition 4 create a causal set with a particular structure, a distributive lattice. If there is no meet or join, they

are added to the causal set. Thus, a POS that is not a lattice is changed into a lattice. In particular, once a causal set becomes a distributive lattice, it is not changed again, and the structure is maintained (Fig. 4).

A distributive lattice is verified to be a lattice that contains no  $M_3$  and  $N_5$  as a sub-lattice (a subset of a lattice that is closed with respect to a join and meet). The structure of  $M_3$  and  $N_5$  are shown in Fig. 5. Given  $M_3$  and  $N_5$  as the initial causal sets, dynamics modify the causal set into a lattice without  $M_3$  and  $N_5$ . As a result, the causal set evolves into a distributive lattice.

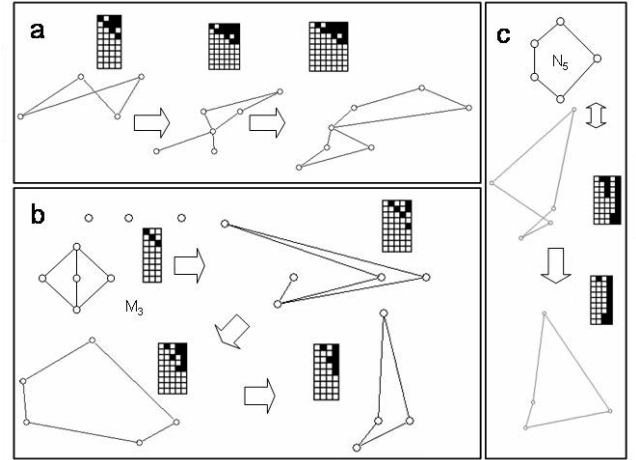

Figure 5. a. The initial POS is developed into a distributive lattice (DL). b.  $M_3$  has also fallen into DL. The arrow represents time development.

Figure 6. Distributivity plotted against time for a causal set (left) and the rate of completion against time (right). The black line corresponds to an evolutionary topological system, and the red and blue lines correspond to the control experiments. The initial set consists of 240 binary sequences.

To estimate how a causal set converges into a distributive lattice, we define distributivity for a causal set  $P^t$ : three elements  $a, b$  and  $c$ , are randomly chosen, and whether  $a \wedge (b \vee c) = (a \wedge b) \vee (a \wedge c)$  is evaluated, as long as the required meet and join exist, for  $K$  times. Distributivity is defined by

the number of equality divided by  $K$ . We also define two control experiments to compare with the evolutionary topological system. The first control dynamic is only the application of completion (i.e., the procedure of adding meet and join) to a causal set,  $P'$ . It does not contain the procedure of (vii) in definition 4. The second control dynamic also does not contain (vii), and the completion is indeed defined by a union and intersection. Thus, the second control dynamic does not contain equations (11) and (12); therefore,  $a \wedge b = a \otimes b$ , and  $a \vee b = a \oplus b$ . If completion is achieved by these procedures, a causal set can become a lattice of sets, which is well known as a distributive lattice.

Figure 7. Distributivity plotted against time for a causal set (left) and the rate of completion against time (right). The black line corresponds to an evolutionary topological system, and the red and blue lines correspond to the control experiments. The initial set consists of 70 binary sequences.

As shown in Fig. 6, the distributivity of a causal set of an evolutionary topological system increases towards a distributive lattice. A causal set consists of 9-bit sequences and 240 elements (sequences) initially. Adding the meet and join and removing elements that do not satisfy the changeability increases the distributivity. Compared with the evolutionary topological system, the two control experiments never increase their distributivity. Even if a meet and join are added in the form of an intersection and union, respectively, in the second control dynamic, adding a new element as the join and/or meet entails another requirement to create the join and/or meet. Thus, completion cannot be achieved, and the distributivity is not increased. If the number of initial causal sets is small, the tendency of increasing distributivity is also found (Fig. 7).

### Distributivity of a causal set

An evolutionary topological system can converge into a distributive lattice. Because of the restricted changeability of join and disjunction and of meet and conjunction, when the system reaches a distributive lattice can be verified.

**Proposition 5 (Evolutionary topological system)** An evolutionary topological system defined by  $\langle P', \uparrow P', \in, F \rangle$  will converge into a distributive lattice.

**Proof. (i)** The case is that  $b \vee c \geq a$  and  $a \wedge b$  is an anti-chain of  $a \wedge c$  but not  $b \geq a$  or  $c \geq a, b$  (i.e.,  $b \vee c \in \uparrow a \Rightarrow b \cup c \in \uparrow a$  does not hold, but procedure (vii) in definition 4 is not applied). This case is shown in Fig. 8. This case leads to a distributive sub-lattice by adding the meet,  $b \wedge c$ , which can be achieved at any point.

Figure 8. The case that  $b \vee c \geq a$  and that  $a \wedge b$  is an anti-chain of  $a \wedge c$  but not  $b \geq a$  or  $c \geq a, b$  (above). The case that  $b \vee c \geq a$  and that  $a \wedge b$  is not an anti-chain of  $a \wedge c$ ,  $b \geq a$  or  $c \geq a$  (below).

(ii) The case that  $b \vee c \geq a$  and that  $a \wedge b$  is not an anti-chain of  $a \wedge c$ , and not that  $b \geq a$  or  $c \geq a, b$ . Although this case also allows that  $b \vee c \in \uparrow a \Rightarrow b \cup c \in \uparrow a$  does not hold, the procedure (vii) in definition 4 can be applied, so  $a$  is removed and a distributive sub lattice is then obtained, as shown in Fig. 8 below.

(iii) Another case is from (i) and (ii). Because the statement  $a \wedge (b \vee c) \geq (a \wedge b) \vee (a \wedge c)$  holds in any lattice, we will prove that  $a \wedge (b \vee c) \leq (a \wedge b) \vee (a \wedge c)$ . Because  $a \wedge (b \vee c)$  is a lower bound for  $\{a, b \vee c\}$ , we obtain  $a \wedge (b \vee c) \leq a$  and  $a \wedge (b \vee c) \leq b \vee c$ . In a topological system, it means that

$$a \in \uparrow(a \wedge (b \vee c)) \text{ and } b \vee c \in \uparrow(a \wedge (b \vee c)). \quad (13)$$

Because of the changeability of disjunction and join, we can replace this statement with

$$a \in \uparrow(a \wedge (b \vee c)) \text{ and } (b \in \uparrow(a \wedge (b \vee c)) \text{ or } c \in \uparrow(a \wedge (b \vee c))). \quad (14)$$

Because a logical statement satisfies the distributive law, this equation can be rewritten as  $(a \in \uparrow(a \wedge (b \vee c)) \text{ and } b \in \uparrow(a \wedge (b \vee c))) \text{ or } (a \in \uparrow(a \wedge (b \vee c)) \text{ and } c \in \uparrow(a \wedge (b \vee c)))$ .

Additionally, due to the changeability of conjunction and meet, we obtain

$$a \wedge b \in \uparrow(a \wedge (b \vee c)) \text{ or } a \wedge c \in \uparrow(a \wedge (b \vee c)). \quad (15)$$

By replacing the disjunction with join,

$$(a \wedge b) \vee (a \wedge c) \in \uparrow(a \wedge (b \vee c)). \quad (16)$$

Thus, we finally obtain

$$a \wedge (b \vee c) \leq (a \wedge b) \vee (a \wedge c). \quad (17)$$

**Significance of Distributivity.** What is the significance of a distributive lattice? It is an abstract expression of a way of thinking in which anything can be considered as the result of summation, which is also known as a representation theorem for a distributive lattice (Davey and Priestley, 2002). The theorem states that any distributive lattice can be expressed as a lattice of sets consisting of sets equipped with a join that is defined by a union and meet, which are defined by an intersection.

Figure 9. A distributive lattice (above) can be a lattice of sets (below) (i.e., a join and meet can be defined by a union and intersection, respectively).

Fig. 9 shows a representative example. The above Hasse diagram exemplifies a distributive lattice containing elements that are sets. Notice that join does not equal union and that meet does not equal intersection while meet is  $\{a, b\} \wedge \{b, c\} = \emptyset$  and intersection is  $\{a, b\} \otimes \{b, c\} = \{b\}$  in Fig. 9 (above). Similarly, while  $\{a, b\} \vee \{b, c\} = \{a, b, c, d\}$ ,  $\{a, b\} \oplus \{b, c\} = \{a, b, c\}$ , which explains why the lattice in Fig. 9 (above) is not a lattice of sets. However, this lattice can be represented by a set of lattices by replacing elements with other elements represented in Fig. 9 (below). In this lattice, any meet is defined by an intersection, and any join is defined by a union.

Thus, a distributive lattice is an abstract expression of set-based thinking: a whole system can be reduced to elements, and summing up the elements can create a whole system. There is no non-linear interaction among the elements. Our results, in which an evolutionary topological system evolves towards a distributive lattice, indicate that a cause-effect relationship in space-time can be developed as the simplest logical structure. Although the changeability of disjunction and union (conjunction and meet) can be erroneous, space-time appears to be constructed as an operationally simple cause-effect relationship.

### Out of body experience resulting from the changeability of disjunction and join

An evolutionary topological system is based on the changeability of join and disjunction and of meet and

conjunction. What is the real implementation of the changeability? Although a disjunction or conjunction is a type of distribution or a set of elements in a causal set, join and meet are single elements of a causal set. However, they differ with respect to logical status and can be replaced with each other to improve the conflict between Point and Open Logic. We believe that this changeability plays an essential role in our cognitive system.

**Body image.** The generation of a body image can be one of the examples resulting from the changeability of disjunction and join. In brain science, the relationship between body schema (operational body) and body image (body owned by oneself) is investigated. Even a hermit crab can detect a sudden change in the carried shell in terms of size, thereby changing its method of walking based on the shell size (Sonoda et al., 2013). This observation implies that body schema appears to affect body image and that both always interact with each other.

Although a body schema is based on controlling a point, a body image is a collection of parts as a whole. The former is related to Point Logic, and the latter is related to Open Logic. Thus, the interaction between body image and schema is also faced with the conflict between Point and Open Logic.

Figure 10. A model for the creation of a body image resulting from the changeability of disjunction and join. The black squares are pillars or obstacles.

Imagine an infant who operates his own body. He first assumes that he is just a point and has to control this point to walk between pillars in his room (Fig. 10 left). He never controls this point in a strict sense. However, he attempts to move this point to a central point between the pillars, and the point is occasionally at a location  $a$  and occasionally at  $b$  (because he ignores his body size). As a result, a body can be at  $a$  or  $b$ . However, if an idea occurs to him that the possibility of  $a$  or  $b$  itself can be a “big” point, then a point has to be something big that is at  $a$  and  $b$  at the same time (Fig. 10 right). Thus, the body image was created as a join resulting from disjunction.

**Out of body experience.** According to our evolutionary topological system, two events that are exclusive of each other can be replaced with a single event, which can satisfy two

exclusive events in a causal set. Thus, we can design an artificial space-time event appearing from the changeability of disjunction and join. Using a variation of the Substitutional Reality (SR) system (Suzuki et al., 2012), we construct the sensation of an out-of-body experience, as shown in Fig. 11.

The system consists of a head-mounted display (HMD) fitted with a video camera at the front center (subjective-eye camera), a panoramic video camera (objective-eye camera) and a control computer. In our preliminary experiment, a participant sitting in a room first sees an experimenter in front of him with his naked eyes. Then he wears the HMD and see the experimenter through the subjective-eye camera. This causal relationship is shown as an event,  $a \leq a'$  (Fig. 11). Then, the scene pre-recorded by the objective eye camera set in front of the participant is projected in the HMD. Thus, the participant sees himself appearing and wearing the HMD, corresponding a causal relationship of  $b \leq b'$  (Fig. 11). With several virtual-reality-inspired tricks, even in the objective view he is able to look around freely as in the subjective view.

Figure 11. Design for the “Out-of-Body Experience (OBE)” in an evolutionary topological system.

The subjective view,  $a'$ , and the objective view,  $b'$ , are exclusive of each other, although they are both sides of the same coin –“now”. They are not united by a single event in this situation. However, if the subject experiences a smooth transition between objective and subjective view (by changing the objective camera position and using several video effects), represented by the blue arrows in Fig. 11, he feels as if he is seeing himself in his subjective view. That feeling corresponds to the replacement of  $a' \cup b'$  by a single event,  $a' \vee b'$ . According to his verbal report, he feels an OBE which is not just an experience of seeing himself. Instead, he feels as if he has created another perspective by his imagination (Fig. 11). Therefore, in this feeling, exclusive subjective and objective scenes can be considered to be united as a single event, which is different from the feeling experienced in a previous experiment (Lenggenhager et al., 2007).

## Conclusion

A causal set developed in quantum physics attempts to describe a space-time from an observer’s view. If so, we have to pay attention to the interaction between the causal relationship and an observer that is a computation and/or logical operation in a space-time equipped with a causal relationship. For this purpose, we describe a causal set and its semantics as a topological system consisting of Point and Open logic.

The binary relationship between Point and Open Logic can derive a conflict that can be improved by restricting logical operations. We here, however, propose an evolutionary topological system in which a conflict between Point and Open Logic is locally and temporally improved that can generate an artificial causal relationship. This local improvement is implemented by the changeability between join and disjunction and between meet and conjunction represented by the replacement of a set with an element to keep non-restricted logical operations.

We show and verify that a causal set of the evolutionary topological system can converge to a distributive lattice that is an abstract expression of the simplest logical operation for summation. We also show that the changeability of disjunction and join can generate abnormal space-time feelings, such as an out-of-body experience. We can design both normal and abnormal artificial space-time based on an evolutionary topological system.

## "Artificial spores" - hybrid alginate microcapsules with encapsulated yeast cells

Jitka Čejková, Petra Haufová, Damian Gorný and František Štěpánek

Chemical Robotics Laboratory, Institute of Chemical Technology Prague, Technická 3, 166 28 Prague 6, Czech Republic  
Jitka.Cejkova@vscht.cz

### Abstract

The present work describes the fabrication, structure and functional characterization of composite microcapsules containing encapsulated viable yeast cells, fluorescently labeled liposomes and magnetic nanoparticles embedded in a calcium alginate matrix produced by ink-jet printing. The proliferation of the encapsulated cells under favorable conditions (presence of nutrients, temperature) is used as a biological trigger for the disintegration of the microcapsules and the liberation of the encapsulated sub-micron particles. The principle of "artificial spores", *i.e.* the possibility to repeatedly stop and restart the cell proliferation process has also been demonstrated. Such biologically triggered release from composite microcapsules is novel and offers potentially interesting applications such as autonomous release of bactericides or fungicides only under conditions that are favorable for microbial growth.

### Introduction

In biology, a spore is defined as a reproductive structure that is adapted for dispersion and survival for extended periods of time in unfavorable conditions. Once conditions are favorable, spores can develop into new organisms. The activators of such a transformation from spore to cell could be *e.g.* nutrients, temperature, pH, or combination of these parameters. There are several reasons why the spores are formed in the nature:

- (i) Spores allow the organisms to survive for many (in some cases, millions of) years under adverse conditions, thus they serve as storage system for genetic information.
- (ii) Spores shield cellular components in harsh conditions, and so spores have the protection function.
- (iii) A spore must somehow "arrive" at a location and be there at a time favorable for germination and growth. Some spores have flagella or other organelles that serve for the species dispersion to longer distances and new areas. Therefore spores serve as transporters of genetic information.

In present work we adopted the idea of spores and created hybrid alginate microcapsules with embedded yeast cells that are long-term stable and inactive and perform specific target mission only after activation by changing the conditions in their surround. The target aim is to disintegrate and liberate and disperse the encapsulated content in proper time. The principle of such artificial spores is described in Figure 1. Under unfavorable conditions (absence of nutrients) no cell division of embedded yeast occurs and the composite microcapsules are stable in aqueous medium for extended periods of time without disintegration or release of their

content. Once the microcapsules encounter favorable conditions (presence of nutrients, here provided by a culture medium), cell division and growth causes a rupture of the alginate capsule and release of the embedded components. Liposomes loaded with fluorescein represent a model "active" particulate substance that is to be liberated from the composite microcapsules. Additionally, iron oxide magnetic nanoparticles were also embedded within the composite microcapsules to facilitate their manipulation and separation by a magnetic field.

The present paper focuses mainly on problem (i) described above. Artificial spores were fabricated and their stability and inactivity for long time were investigated. The ability to activate in suitable conditions (in this case nutrients additions) was studied. Artificial spores cultivated in growth medium showed the ability to disintegrate and release embedded object into the surround. This mechanism acts as a biological trigger for controlled opening of the microcapsule.

Further we concentrated on the protection function of spores (task (ii) above). Artificial spores were coated by solid silica shell and the viability of encapsulate yeast was tested. Although the coating process does not kill the cells, the cell growth in the microcapsules was not sufficient for the microcapsule disruption. Unfortunately this way of protection shell formation seems to be unsuitable.

Such artificial spores will find applications in biologically triggered controlled delivery *e.g.* of natural fragrances or benign fungicides. Another application of these objects could be as intelligent indicators of storage quality.

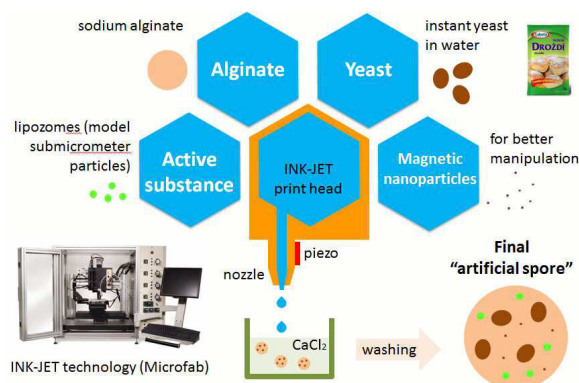

**Figure 1:** Schematic principle of artificial spore rupture and liberation of an active substance into the environment caused by yeast cell growth in the culture medium.

## Experimental

### Materials

Sodium alginate, calcium chloride ( $\text{CaCl}_2$ ), (3-aminopropyl) trimethoxysilane (AMPS), tetramethoxysilane (TMOS), *n*-hexane, [7 - diethylaminocoumarin - 3 - carboxylic acid] (DEAC), fluorescein diacetate (FDA), yeast extract and glucose were purchased from Sigma-Aldrich. Instant yeast cells (Labeta a.s., Czech Republic) were suspended in deionized water in various concentrations (1 mg of dry powder corresponds to  $3 \times 10^7$  cells). Hydrophilic iron oxide nanoparticles were prepared according to a synthesis described in (Tokárová et al., 2012). Fluorescently labeled liposomes (molar ratio of DPPC : cholesterol was 2:1) were synthesized in the same way as described in (Ullrich et al., 2013). Deionized water was produced by a ionex filter (Aqual 25).

**Figure 2:** Schema of artificial spore preparation. Solution of sodium alginate, yeast cells, liposomes and magnetic nanoparticles is by means of Ink-Jet printing technology dropped into  $\text{CaCl}_2$  solution. Precipitated calcium alginate microcapsules are subsequently washed.

### Artificial spore preparation

All artificial spores were produced by inkjet printing (Dohnal and Štěpánek, 2010). A piezoelectric drop-on-demand print-head type M5-ABP-01-80-6MX supplied by Microfab, Inc. (Plano, Texas, USA) was used, coupled with a control unit type JetDrive III and a pressure controller type CT-PT-01 also supplied by Microfab, Inc. 2 ml of aqueous solutions of 2% (w/w) sodium alginate and 2 ml of aqueous suspension of yeast cells were mixed and printed into approximately 50 ml of aqueous solution of 2% (w/w)  $\text{CaCl}_2$  where a rapid ionic cross-linking of the microdroplets occurred. The receiving  $\text{CaCl}_2$  solution was constantly agitated to avoid microdroplet coalescence after impact. To prepare the magnetic microcapsules, one half of the cell suspension was replaced by citrate-stabilized iron oxide nanoparticle dispersion in water (15 mg/ml). The solution for printing of magnetic capsules containing liposomes was mixed from a sodium alginate solution, the cell suspension, the iron oxide nanoparticle solution and a liposome solution in the volume

ratio 4:1:1:2. Cross-linked calcium alginate microcapsules were separated from the  $\text{CaCl}_2$  solution by using filter or magnet and suspended in deionized water in which they were stored at room temperature until further use. In this state the composite microcapsules were stable for up to 4 months without any significant loss of yeast cell viability or leakage from the liposomes.

### Coating of artificial spores by silica shell

The silica shell was formed by a sol-gel process according to our previous procedure (Haufova et al., 2012) derived from the work of Sakai (Sakai et al., 2001): the alginate microcapsules were suspended in *n*-hexane and kept at  $4^\circ\text{C}$  in an ice-bath. AMPS and TMOS were then added to *n*-hexane containing the alginate particles. AMPS was added first and stirred for 1 min, followed by TMOS and stirring for another 1 min. The thickness of the silica layer is influenced by the quantity of the silica precursors (AMPS and TMOS). The volume ratios of 10:14:0.8:0.6 for alginate:*n*-hexane:AMPS:TMOS were used in our case. Based on the assumption of complete hydrolysis of the alkoxysilanes and average alginate particle size of  $70\ \mu\text{m}$ , the resulting thickness of the deposited silica layer is  $0.23\ \mu\text{m}$ . The resulting microparticles were then rinse with 1.0 wt.%  $\text{CaCl}_2$  solution and then kept in deionized water in a fridge for further use. All the procedures/solutions were kept cold (at  $4^\circ\text{C}$ ) to enhance the stability of liposomes.

The synthesis of fluorescently labeled silica nanoparticles is specified in (Čejková et al., 2010) with the exception that the fluorescent dye DEAC was used instead of fluorescein isothiocyanate (FITC). For subsequent visualization of the silica layer, the pre-synthesized fluorescently labeled silica nanoparticles ( $\text{SiO}_2$ -DEAC nano) were added into the silica layer formed by the sol-gel process. 100 mg of  $\text{SiO}_2$ -DEAC nanoparticles was mixed with 1 ml AMPS for 24 hours prior the further sol-gel procedure. The mean diameter of the  $\text{SiO}_2$ -DEAC nanoparticles was 150 nm.

### Artificial spore characterization

The artificial spores were characterized by means of inverted optical microscope (Olympus CK40) and a laser scanning confocal microscope - LSCM (Olympus Fluoview FV1000). The particle size was evaluated by laser diffraction (Horiba Partica LA 950/V2). The viability of yeast cells was confirmed by using the standard fluorescein diacetate solution method.

### Yeast cell division and artificial spore disruption study

For a study of the cell division and disintegration of artificial spores, the composite microcapsules were placed into a Petri dish containing a culture medium (consisting of glucose in a concentration of 10 g/l and yeast extract in a concentration of 5 g/l) and monitored by an optical microscope for 24 hours. The cell growth curves were measured by means of visible spectrophotometer (Specord 205 BU, Analytik Jena, Germany); the wavelength used for the measurement of optical density was 600 nm ( $\text{OD}_{600}$ ).

## Results and discussion

### Artificial spores characterization

The drop-on-demand inkjet technology was used for the formation of calcium alginate microcapsules with embedded yeast cells by ejecting droplets of a sodium alginate precursor into a pool of calcium chloride solution. The shape of the formed microcapsules was mostly spherical, however, some of them were distorted (flattened) due to droplet deformation upon landing into the  $\text{CaCl}_2$  solution.

The viability of yeast cells in the composite microcapsules was confirmed by using fluorescein diacetate (FDA). This colorless compound exhibits no fluorescence, however, it is known that it diffuses through cell membrane and living cells are able to hydrolyze it by their enzymatic apparatus and transform FDA into fluorescein (Adam and Duncan, 2001). Typically, 2 ml of microcapsule suspension were incubated with a few droplets of FDA in acetone for 20 minutes, then washed and observed under LSCM. By this test it was proven that the cells are able to retain their viability during the ink-jet printing process. The microcapsules after one month of their fabrication and storage in water that were incubated with FDA show in LSCM images green spots. These spots correspond to living cells, which confirms that the cell viability is preserved for many weeks.

The hybrid microcapsules with embedded yeast cells were stored in water for few weeks and no microcapsule changes and cell division in capsules were observed. Radical changes occurred after incubation with growth medium containing yeast extract and glucose.

To observe the cell division of encapsulated yeast, composite microcapsules were suspended in Petri dish with growth medium and placed under microscope. Images in 1-minutes intervals were grabbed for at least 24 hours. Typical results are shown in Figure 3 for microcapsules containing yeast cells in concentration of  $3.75 \times 10^8$  cell/ml.

**Figure 3:** Yeast cell division in alginate microcapsules incubated in a Petri dish with culture medium. Concentration of yeast cells in prepared microcapsules  $3.75 \times 10^8$  cell/ml. Scale bar represent 100  $\mu\text{m}$ .

Figure 3 shows the changes of microcapsules in various times in static conditions in a Petri dish with cultivation medium. After fabrication the cell concentration in microcapsules corresponded to the cell concentration in alginate matrix that was printed into  $\text{CaCl}_2$  solution. Time  $t = 0$  h corresponds to placing of microcapsules into cultivation medium. Few hours after incubation in growth medium, buds on cells appeared and cells started to divide. Around the time  $t = 7$  h, the cell division was highly developed. Around the time  $t = 15$  h, alginate microcapsules

were almost full of cells and at time  $t = 18$  h first ruptures of composite microcapsules started. Due to intensive cell division all microcapsules disintegrate and almost no compact round microcapsules were evident at time  $t = 24$  h. In the Petri dish only clusters of yeast cells were present. This experiment confirmed the idea of artificial spore – microcapsules are for long time stable and after external condition changes ruptured and released their content.

Further the growth curves of cells in alginate microcapsules were measured by using visible spectrophotometry as a function of optical density at the wavelength 600 nm. First few hours no changes were evident, because yeast cells were still in lag phase of their growth, they adapted themselves to growth conditions and rarely cells divided. About at the time  $t = 7$  h, the cells entered into the exponential phase of their growth which corresponded with rapid increase in measured absorbance. Approximately until the time  $t = 24$  h the increase of absorbance is evident, which shows the cell division. After the time  $t = 24$  h, the absorbance did not increase, because cells entered into the stationary phase of their growth due to the lack of nutrients.

As was shown above, composite microcapsules are stable in water, whereas after cultivation in growth medium they are able to disintegrate and release their content. To confirm this fact, the liberation of fluorescently labeled liposomes was observed by laser scanning confocal microscope. Directly after their fabrication, the fluorescence signal is obtained only in microcapsules and this confirms the successful encapsulation of liposomes into microcapsules. The same microcapsules imaged one day after fabrication and storage in pure water show the fluorescence signal again only in microcapsules, no liberation of liposomes from microcapsules occurred. On the other hand, after cultivation of microcapsules in growth medium, the cells divide and cause the rupture of capsules, the liberation of all encapsulated substances and their release into the surround. After one day of incubation in culture medium no compact microcapsules were present, only the clusters of cells were evident and the fluorescence signal was detectable from whole medium because the liposomes were released during the microcapsule disintegration.

### Temperature effects on artificial spore germination

In biology, a spore is defined as a reproductive structure that is adapted for dispersion and survival for extended periods of time in unfavorable conditions. The interesting property of the transformation of spores into cellular entities is as follows: once the conditions seem to be suitable for germination, the spores enter a lag phase and activate specific genes that trigger certain signal pathways leading to swelling and cell emergence. Once a spore has swollen, germination becomes irreversible, but during the lag phase activated spores can return to dormancy (Van Dijken and Van Haastert, 2001).

To cover the idea of “artificial spores”, additional experiments with switching favorable/unfavorable conditions were performed. In previous section the experiments with nutrient additions were described. It was shown, that the growth medium can start the process of cell division with consequent microcapsule rupture. We were interested if it is

possible to stop the division process anyway and then to trigger the growth again. Therefore following experiments with temperature changes were done.

The experiment mimicking spore response to conditions changes was performed in spectrophotometer equipped with heating/cooling facility. The growth curves were measured and with temperature changes compared. The experiment started at unfavorable conditions, where microcapsules were stored in water (without nutrients). The first change consisted in placing of capsules in the culture medium at temperature 30°C (corresponding to time  $t = 0$  h in the growth curves in Figure 4). Although they had enough of nutrients and the temperature was acceptable, the first few hours the yeast embedded in microcapsule were still dormant, because they were in the lag phase. When they entered the exponentially phase of their growth, we have decreased the temperature rapidly to 8°C. Such a temperature shock stopped the cell growth resulting in a return into dormancy of microcapsules. During this time no change of optical density was observed corresponding to no division of cells. This horizontal line in the growth curve confirmed the possibility to paralyze artificial spores with temperature decrease that represents coming back of unfavorable conditions. To provide the better conditions again, the temperature was increased back to 30°C. Such a sudden suitable condition establishment lead to rapid cell growth again. The next temperature decrease caused the next interruption of cell division. The example of three repetitions heating/cooling represents Figure 4(B) shows the possibility to “freeze” the cell growth in microcapsule for almost two days.

**Figure 4:** Interruption of yeast growth by temperature decrease and resumption of growth by increase of temperature. (A) Three interruption of cell growth by three temperature decreases (at time 11-16 h, 20-25 h, 35-40 h). (B) Long cell growth interruption for almost two days (8-48 h).

### Silica shell of artificial spores

To develop the concept of artificial spore it is necessary to develop the strategy to coat the particle with any hard thin shell that could protect the encapsulated content. For this reason we decided to cover the hybrid alginate microcapsule by silica shell because of our previous experience with this process (Haufová et al., 2010).

Figure 5 represents image of microcapsules covered by thin fluorescently labeled silica layer (it is visualized by blue color). Green spots correspond to viable encapsulated yeast cells visualized by using FDA as described in previous

sections. It was proven that the sol-gel coating process in harsh conditions (temperature 4°C, in *n*-hexane solution) does not kill all the cells and some cells are still viable. It can be concluded that at least some of the yeast cells were able to survive both the inkjet printing and the silica coating processes, although there seems to be also a fraction of dead (non-fluorescent) cells. However the coating lead to microcapsule shrinkage (*ca* to 30 µm compared to 80 µm original diameter).

**Figure 5:** Laser scanning confocal microscopic images of alginate microcapsules with encapsulated yeast cells (viable cells visualized by green color) and covered by fluorescently labeled silica shell (blue color).

Further we focused on cell division in silica-coated microcapsules. Figure 6 summarized the results of silica-coated artificial spores' cultivation in growth medium. It is evident, that yeast cells entrapped on the surface of microcapsules are able to divide and growth freely in surrounding medium, however the growth of cells inside the microcapsule is not sufficient to microcapsule disruption and following rupture. Unfortunately these results exclude the sol-gel silica coating method as a suitable process for protecting surface layer formation. Our future work will focus on other cover techniques, such as layer-by-layer method.

### Dry artificial spores

All experiments described above were performed in aqueous conditions. Artificial spores were fabricated and stored in aqueous solutions and never during their studies were dried. Following test focused on the properties changes after particle drying.

The artificial spores were air dried and Figure 7 represents microscopic images of their rehydration. In (A) dry shrunken microcapsules are displayed. Figure (B) shows the result of microcapsule incubation in water for 1 hour. Dry alginate is not able to swell in pure water and microcapsule retain in the shrunken state. On the other hand, growth medium containing various ions is able to facilitate the microcapsule swelling (Figure C). Unfortunately, cell division in rehydrated artificial spores was not sufficient for microcapsule rupture. This observation recommends the artificial cells applications in hydrated state without any drying step.

**Figure 6:** Cultivation of silica-coated artificial spores in growth medium. Optical microscope images from times  $t = 0$ , 6 and 36 hours after placing into the medium.

### Conclusions

We fabricated a new type of microcapsules with embedded microorganisms that can locally liberate sub-micrometer objects, and act as a biological trigger for controlled opening of the microcapsule. Such a hybrid microparticle cover the idea of artificial spore, that is inactive for long time without any changes and start to rupture after external condition changes (here nutrient addition). Artificial spores prepared here were able to liberate encapsulate model substance in form of liposomes. It was shown, that silica coating by means of so-gel process does not allow the microcapsule rupture as in the case without any shell presence. Further it was observed, that also dried artificial spores are not able to rupture after rehydration in cultivation medium.

Our future work will focus on microcapsule covering to form a shell that will protect the alginate and encapsulated objects and subsequently will not prohibit the particle rupture. Because the rupture of capsules is also impossible for particles that were dried, we will concentrate to find applications for artificial spores in aqueous solution, such as in biologically triggered controlled delivery, *e.g.* of natural fragrances or benign fungicides or as quality indicators.

**Figure 7:** Microscopic images of rehydration of dry artificial spores (A) in water (B) and in growth medium (C) after 1 hour.

### **Abstract**

Cell membranes are essential part of living cells. They are important as the envelope which encapsulate the biochemical systems within them and distinguish “self” components from “not-self” surrounding environment. Furthermore, cell membranes function as an interface which exchange materials between inside and outside of the cell, sense external environment, and transmit signals to inside systems to response the circumstance. In the field of synthetic biology, liposome (lipid membrane vesicle) has been widely used as a model of cell membrane. Although liposome is certainly a good model as for cell envelope, it is not satisfying the biochemical functions of cell membranes. Since the most of cell membrane functions are led by membrane embedded proteins, we should combine membrane proteins with liposome to construct more feasible artificial cell membranes. In this research, we aim to equip membrane machinery on liposome membrane using in vitro gene expression system.

We show that a membrane machinery Sec translocon<sup>1</sup>, which conducts membrane secretion and insertion of protein (Figure 1), has been synthesized onto the liposome membrane from its template DNAs. The gene expression was performed with the cell-free protein synthesis system, PURE system<sup>2</sup>. The PURE system is a reconstructed transcription/translation system that actualizes the phenomenon of Central Dogma (DNA-RNA-protein) in vitro with the minimal number of factors. Synthesized Sec proteins spontaneously localized at lipid bilayer and about 80nM Sec translocon were produced in functional state. This indicates that 2-3 Sec translocon were allocated to one liposome membrane based on a sequence of statistical calculations. Although the population density of the produced Sec translocon was not so high, a substantial peptides secretion activity of the Sec translocon was detected by biochemical assays. The specific activity of the synthesized Sec translocon was comparable to that of native Sec translocon isolated from cells in the function of protein secretion. In addition, the synthesized Sec translocon was able to conduct membrane insertion of a multi-spanning protein. These results indicate that the artificially synthesized Sec translocon is functional both in secretion and insertion. It should be noted that the formation of Sec translocon was achieved in self-assembly process.

Our results demonstrate that the functional Sec translocon has been constructed in totally synthetic manner. Although the

protein synthesis in this study were performed on the outside of the liposomes, the same reaction would be occurred inside liposomes, for instance giant unilamellar vesicles that can effectively encapsulate a cell-free system and DNA<sup>3</sup>. More importantly, our results raise a possibility that various membrane proteins can be subsequently produced in liposome membrane by primarily constructed Sec translocon, and eventually non-functional liposomes will gain divers bio-functions that are essential for a living artificial cell.

## Experimental studied on growing chemical organisms.

Jerzy Maselko<sup>1</sup>, James Pantaleone<sup>2</sup>, Vitaliy Kaminker<sup>2</sup>

1. Chemistry Department, University of Alaska, Anchorage, USA
2. Department of Physics/Astronomy, University of Alaska, Anchorage, USA

The subject of this conference is: ‘Attempts to design and build artificial systems that display properties of organisms’. Two hundred years ago, the philosopher Immanuel Kant wrote the following:

‘Property of life: A self-propagating organization of processes.’

The difference between biological organisms and the complex chemical systems made by humans cannot be underestimated. The former contain such a large number of physical and chemical processes, each marked by incredible spatial and temporal organization and preciseness, that as of yet, their artificial reproduction is unachievable.

There remains, in addition, a gulf between biological growth and human controlled technology. These methods are not compatible. Human built complex chemical systems are assembled, whereas the biological systems are grown. Even the simplest biological cell cannot be disassembled and later reconstructed as if it were an AK-47.

Few known phenomena show promise of bridging this gulf; one of these is the ‘Chemical Garden’. In such systems, chemical reactions between a few elements drive fluid flow to spontaneously form precipitation structures. These structures can be grown from a ‘seed’, and the specific structure produced closely correlates to the composition of the seed and the environment. Chemical gardens have growth trajectories that span a vast morphological space, which includes hierarchical structures and also structures that move (chemical motors).

Among the first works devoted to these systems was published by Leduc in 1911 under the title “The Mechanism of Life”<sup>1</sup>. Leduc recognized the similarity of chemical gardens with biological systems and believed that this similarity could teach us something about the origin of life. In his book, he wrote that “The study of synthetic biology is therefore the study of physical forces and conditions which can produce cavities surrounded by osmotic membranes... and specialized their functions of living beings.”

Examples of the structures that can be grown in this manner are presented below.

Figure1: Examples of complex structures that grow in simple chemical systems.

In each of these systems, growth is controlled by a complicated network of precisely organized physical and chemical processes. This growth is caused by a chain reaction; different potential gradients form structures that are, in turn, sources of new potential gradients. Thus we have a sequence of structures and processes: Structure follows process, gradient follows process, structure follows gradient, and so on. In these complex networks, different trajectories lead to different structures. Trajectories can be controlled by environment or seed composition. The growing process is often characterized by formation of templates that control formation of the next structure. The template may, depending on the trajectories, form different structures. Some structures may undergo metamorphosis where the entire structure changes (copper-oxalate system).

The process of growth is hierarchical, forming a network. Simple elements at lower levels form more complex structures at the higher levels. These, in turn, function as simple building blocks for even higher levels. So far, we have grown chemical systems with eight hierarchy levels. This is only the beginning. By changing system parameters, we can form different chemical building blocks, thus changing the trajectory. Trajectories may also be changed by catalysts or inhibitors (aluminum silicate system).

In most cases, the growing network can be divided into three parts: the seed, the construction, and the final structure. The seed forms an initial cell, where the initial potential gradients are making initial processes. The next part of network is construction, where the cascade of different structures are built. These systems are open ended, making it impossible to predict the final structure. Usually, the structure is finalized when the network has a loop that results in termination of structure growth.

Sometimes we observe the formation of a whole that may perform certain tasks. This part of the network is operational. It controls the task. Examples are cells that move up and down. This process is controlled by many chemical and physical sub-processes forming a loop (aluminum-carbonate-hydroxide system). Under another condition, this system may construct more complex structures that remain, made by humans, complex curtains.

The Chemical Garden and related structures are chemical systems bridging living and nonliving matter. They allow us to study a much simpler analogue to biological systems. The difference is the lack of DNA and genetic-informational systems that have very complex functions and control mechanisms. It may be said that chemical organisms are biological systems where DNA has been removed after formation of all proteins.

Mastering the growth of these complex chemical organisms may be the beginning of a new technology.

### Abstract

In this paper, we present a series of experiments on the automated classification of Cassin's Vireo individuals from song phrases using support vector machines and from sequences of song phrases using hidden Markov models. Experimental results show that accurate classification of bird individuals can be achieved using these two different levels of description of bird songs.

### Introduction

Understanding the structure and function of bird songs is a long-sought goal in ecology research. Recent advances in sensor arrays, machine learning and computational linguistics finally make the achievement of this goal feasible. Understanding bird songs may also prove helpful in guiding the construction of artifacts that possess high-level communication abilities.

Over the last few years we have collected very large amounts of bird song recordings from acoustic sensor arrays in a variety of natural settings. This data have been processed by localizing source with beamforming, then filtering out noise, identifying events of interest, and then classifying them according to species and individual, and combining that with behavioral observations in a large database.

Our previous work on acoustic classification of birds has been successful at recognizing several species of antbirds and antbird individuals in a Mexican rainforest, Vallejo and Taylor (2009), Trifa et al. (2008). These birds possess quite simple, but distinctive, songs which are thought to be innate. In contrast, songbirds have a vocal organ highly developed that normally produce the relatively long and complicated vocalizations which are usually learnt, Catchpole and Slater (2008).

Particularly, the work presented here aims at exploring to what extent the methods we have used in the past are able to address and conduct the classification of songbird individuals. Further, it would be very useful for our research goals to understand the classification capabilities and limitations of sensor arrays when dealing with different levels of description of bird songs –song phrases, sequences of song

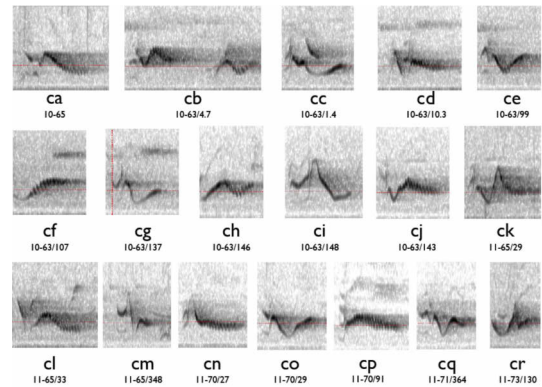

Figure 1: A subset of the CaVi phrases

phrases, etc. Toward this end, here we explore on classification of Cassin's Vireo (CaVi) individuals from song phrases using support vector machines (SVMs) and from sequences of song phrases using hidden Markov models (HMMs).

### Identifying CaVi individuals from song phrases using SVMs

The species of birds in our analysis have been the Cassin's Vireo (*Vireo cassinii*) a North American songbird, ranging from southern British Columbia in Canada through the western coastal states of the United States. The song consists of sequences of short, rough whistled phrases of several notes. The songs used in this work were recorded from April 2010 to July 2012, by Martin L. Cody. Examples of the CaVi songs are posted on <http://taylor0.biology.ucla.edu/al/bioacoustics/>.

A collection of 65 different phrases was identified by visual inspection of the sonograms. The sonograms of some of the CaVi phrases are in Figure 1, above. An example of extracted song grammar for a sample of the dataset is described by the Markov chain of figure 2. Samples of 12-53 phrases from each of the 12 individuals were included in the dataset. The sonogram of each phrase was measured for 124 traits using the Marsyas software package, Tzanetakis and Cook

Figure 2: Markov chain of CaVi song. The states correspond to song phrases and the arrows indicate the transition probabilities among phrases

(1999) so that each song was represented by a vector. From these vectors, principal components were extracted and represented by a vector of 26 principal components.

Classification of individuals by SVMs was conducted using the Weka package, Witten et al. (2011). A radial basis function (RBF) kernel was used for the experiments. 10-fold cross-validation was conducted to find appropriate kernel parameters. Training was performed using the obtained kernel parameters on the training set. Testing was conducted using data samples not included in the training set. The classification results obtained in our experiments are in Figure 3.

### Identifying Cassin's Vireo individuals from sequences of song phrases using HMMs

Samples of 44 songs represented by sequences of phrases from each of the 12 individuals were included in the data set. Classification of individuals by HMMs was conducted using the Accord package <http://accord.googlecode.com/>. The Baum-Welch training algorithm was used for the experiments. A collection of training and validation experiments was conducted using this dataset. The classification results obtained in our experiments for each of the CaVi 12 individuals are presented in Figure 3. Results for HMMs are shown in gray, while those for SVMs in black. In nearly all cases the precision of classification was high - 90% or better. The HMMs appear to achieve slightly higher precision for practically all phrase types except for two, where there results were quite poor, only 40-50%, while the SVM results remained high throughout.

### Conclusions

Here we show that is feasible to discriminate songbirds individuals with similar accuracy from different levels of descriptions of birds songs –on the one hand, using their spectral and temporal acoustic features, and on the other hand, using the composition of their sequences of phrases.

The results presented are currently being analyzed by computational-linguistic tools to identify the syntax of the songs, and combined with information about the context in

Figure 3: Classification of CaVi individuals. HMMs are shown in gray, those for SVMs in black

which they occurred, then analyzed by new software methods to identify the meaning of those songs. These methods will draw inferences from those meanings and explore consequences for individual and community ecology.

We believe this work will contribute to the recognition of very sophisticated signaling strategies and syntactic structures in non-human species. In addition, the work reported here can contribute to expand the range of engineering with voice recognition and classification, which so far has been restricted almost exclusively to humans. They hold promise to elucidate the fundamental properties of bird language. These results could then be useful to make progress on enabling high-level communication in artificial agents.

## **Prebiotic Organic Microstructures as Model Protocells**

Henderson Cleaves and Neil Anthony

### **Abstract**

A variety of prebiotic syntheses starting from reduced and gas precursors, or small reactive organic intermediates produce a variety of micron and sub-micron sized organic microstructures, including spheres, filaments and toroids. Many of these structures are hollow, and they display dynamic and reversible self-assembly. We report here some of their physical characteristics that might be compatible with proto-cellular evolution.

## EMANN - a model of emotions in an artificial neural network

Ronald Thenius, Payam Zahadat and Thomas Schmickl

Artificial Life Laboratory, University of Graz, Austria.  
ronald.thenius@uni-graz.at

### Abstract

With the work at hand we want to present a model of a neural system, that is influenced by emotions. This model is based on the state of the art concept of artificial neural networks (ANN) which we improve by adding 'artificial emotions'. The way of the implementation of emotions is based on the research results regarding the biological and biochemical processes modulating neural cells in animals and humans. The described modulation takes place not only on the level of synapses, but also on the level of calculations happening on the membrane of the cell, or the node of the ANN, respectively. The suggested model also includes the biological fact, that neuro modulatory glands (e.g., hypophysis) are mainly controlled by the neuronal system itself. The resulting proposed system is named EMotional Artificial Neural Network (EMANN). It shows that EMANN has different abilities, compared to ANNs without emotions.

### Introduction

This work is mainly inspired by the work of Fellous (Fellous, 1999; Fellous et al., 2002; Fellous, 2009; Arbib and Fellous, 2004), who discussed the necessity of emotions in artificial systems. Fellous and his co-authors argue, that models of emotions can not only be used in artificial systems as a tool (e.g., to organise activity levels of different tasks with a single robot), but also serve as a model for emotions in animals and humans. Fellous described his ideas and requirements about the implementation of emotions in artificial systems as follows:

- Emotions should not be implemented as a separate, specialized module in charge of computing an emotional value on some dimensions.
- Emotions should not simply be the result of cognitive evaluations.
- Emotions are not linear (or non linear) combinations of some pre-specified basic emotions.
- Emotions should be allowed to have their own temporal dynamics, and should be allowed to interact with one another.

With this paper we propose an advanced concept of Artificial Neural Networks (ANN, described in detail in the following), using biological observations as guideline. Please note, that the proposed model was developed for the purpose to simulate emotions, and to investigate features of the interplay of biochemical, neuromodulatory processes with neural system. If and to what extent this is advantageous for technical solutions is topic of ongoing research (as mentioned below).

### Short overview over the state of the art of ANNs

The concept of ANNs was developed in the first half of 20th the century (McCulloch and Pitts, 1943; Rosenblatt, 1958). Since then several variations of ANNs were developed (Jain et al., 1996), be it differential equation based ANNs (CTRNN, by Beer (1995)) or models of spiking ANNs (Hindmarsh and Rose, 1984).

In all this mentioned methods, information is filtered by the ANN without any feedback of the information on the method of processing: The activity of one node influences the activity of another node via the connection of the two nodes. Via this signal transduction the signal is modulated by the weight associated with the regarding link. Manipulations of the process of filtering usually takes place on the level of synapses, and is done during the learning (or evolving) process. Only a few works exist, which try to modulate the process of data processing itself, based on input or output of the network (Neal and Timmis, 2003; Timmis et al., 2009). To our knowledge, no concept was suggested, in which the way of calculation is modulated and controlled by the network itself. From a biological point of view this ability of self-modulation is highly relevant in biological neural networks, and its implementation will add many new features to the concept of ANNs.

### Emotions and neurons in biological brains

On a biological level, moods and emotion can be understood as the condition an animal is in, based on an internal chemical (mostly hormonal) situation. This internal chemical situation modulates mostly all physiological and neural processes, what comes along with a modulation of as-

sociated behavioural phenomena. Examples for this are love (Carter, 1998; Young et al., 2001), fear (LeDoux, 2000; Derntl et al., 2009) and stress (Vermetten and Bremner, 2002). This way the moods influence as well “low-level” social behaviours (e.g., aggression (Pope et al., 2000)) as well as “high level” social behaviours (e.g. trust) (Kosfeld et al., 2005; Donaldson and Young, 2008; Guastella et al., 2008) etc. On a cellular/chemical level the emotional status is the result of a feedback-loop between the neural system and the hormonal system: On one hand the hormones influence the activity of the biological neural system (Derntl et al., 2009; Joëls, 1997), on the other hand the highest unit in the hierarchical cascade of interacting hormone glands (hypophysis, *glandula pituitaria*) is influenced by the central nervous system via the hypothalamus. Please note, that not all emotions emerge from such a feedback loop in the first place, but can also be triggered by other sources, e.g., by the genome directly.

Based on this phenomenon we developed the EMANN system (EMotional Artificial Neural Network), which improves the classical ANN paradigm (Jain et al., 1996) by the ability to develop hormone glands, that influence the abilities of the neural nodes. In this context the “mood” of an EMANN can be understood as the current hormonal status of the network. How much this “mood” influences the current behaviour of the controlled agent is coded into the individual responsiveness of the nodes of the EMANN.

## Method

### The concept

The suggested model is based on standard ANNs (Jain et al., 1996) which are improved by the features of a simulated neuromodulatory hormonal system. The simulated hormonal glands emit a number of virtual hormones, which represent all types of neuromodulators in a biological brain. These virtual hormones influence the behaviour of the individual nodes (which represent the individual cells within a biological neural system), including the synapses, the functions which sum up the inputs of the node, and the output function (which is analogous to the function of the axon hill of the neural cell). In return, the hormone glands are controlled by the neural network: each cell within the described network is able to emit hormones, which turns each node in the network into a possible hormone gland. To enable a virtual cell to react to a given hormonal level, hormonal receptors for every part of the virtual cell are simulated. These hormonal receptors are analogous to surface hormonal receptors in the membrane of biological neurons. A schematic drawing of the concept of ANN and EMANN is depicted in the Figures 1 and 2.

Throughout this paper, ‘node’ and ‘cell’, and also ‘edge’ and ‘synapse’ are used as synonyms. The main difference between the nodes of an ANN and an EMANN is that EMANN does not only map information from an input to an

Figure 1: Schematic drawing of a single node in a state-of-the-art artificial neural network (ANN). The input of a node (*I - III*), which represents cells in a biological neural network, comes from other nodes of the ANN (*IV*) and/or from the input of the ANN. The weights of the edges between the nodes (*I*), representing synapses in the biological counterpart, are usually adapted to a given task by learning algorithms or by using artificial evolutionary methods. The net-function (*II*), modelling the processes in the dendritic part of a biological neuron, sums up the weighted inputs of the node. The out-function (*III*), from a functional point of view the analogon to the axon-hill in the biological neural cell, calculate the new status of the node. For more details about the state of the art in ANNs see (Jain et al., 1996). The solid arrows indicate the flow of information within the system, round edged triangles indicate the weights (synapses) of the node.

output level, but at the same time elements of a feedback system, that change the behaviour of the cells based on dynamic hormone levels. The “out-function” of the ANN differs from the EMANN analogon which is called “Hill-function” since the later is strongly influenced by hormones during runtime, but the former is usually static during runtime.

### From the biological concept to a mathematical representation

As represented in Figure 2, inputs to a cell of an EMANN system first pass through synapses where each synapse contains a weight that can be influenced by hormones (Figure 2:*I*). The value from the synapse then passes a net-function (represented by  $g(X)$  in Figure 2:*II*) and the total value of the net-outputs from all the input synapses is calculated. Finally, this sum passes a hill-function (represented by  $f(X)$  in Figure 2:*III*). The parameters of both net-functions and hill-functions are influenced by hormones.

In the following formal representations,  $W_{i,j}$  represents the weight of  $j$ th input synapse of cell  $i$ . Its value is specified as:

$$W_{i,j}(H) = \theta_{i,j} + \sum_h \phi_{i,j,h} H_h \quad (1)$$

where  $H$  is the set of hormone levels in the system and  $H_h$  is the level of hormone  $h$ .  $\theta_{i,j}$  is a constant weight for  $j$ th synapse of cell  $i$  and  $\phi_{i,j,h}$  is the responsiveness of the synapse to hormone  $h$ .

Figure 2: Schematic drawing of a single cell (analogon to the nodes in a state-of-the-art ANN) in an Emotional Artificial Neural Network (EMANN). In contrast to a state-of-the-art ANN (figure 1) the cell of the EMANN (I-III) is able not only to receive information from the EMANN (IV), or send information to it, but also to produce hormones (VIII). These hormones are represented by global variables, that sum up the hormone output of one time step of all cells of the EMANN (VII, equ. 12). Each cell is influenced by these hormones (IX), be it on the synaptic level (XII, see equ. 1) on the level of the net-function (XI, see equ. 2) or on the level of the hill function (X, see equ. 6). The degree, in which a cell functions as a neural cell or as a gland for a given hormone is determined by weights (V, VI, see equ. 13 and equ 11). Due to the interaction of cellular activity and hormone levels, a feedback arises, that allows to change the method of information processing, based on the information itself. Solid arrows indicate the flow of information within the EMANN (by which the input of the neural net is mapped to the neural output), the dotted lines indicate hormonal modulatory pathways.

An input to cell  $i$  from its  $j$ th synapse is represented by  $X_{i,j}$ . The input passes through the synapses and the net-function  $Net_{i,j}$  that is described by:

$$Net_{i,j}(X, H) = Netk_i(H) \times f(W_{i,j}(H)X_{i,j}) + Netd_i(H), \quad (2)$$

$$Netk_i(H) = \beta_i + \sum_h \eta_{i,h} H_h, \quad (3)$$

$$Netd_i(H) = \alpha_i + \sum_h \kappa_{i,h} H_h, \quad (4)$$

$$f(x) = \begin{cases} 1 & x < -1 \\ -1 & x > 1 \\ x & else \end{cases} \quad (5)$$

where  $\beta_i$  and  $\alpha_i$  are constant parameters of cell  $i$  and  $\eta_{i,h}$  and  $\kappa_{i,h}$  represent influences of hormone  $h$  on the net-function of the cell.

The net-outputs are then summed up and pass the hill-function and then produce output of the cell that is described as follows:

$$Hill_i(X, H) = Hillk_i(H) \times f\left(\sum_j Net_{i,j}(X, H)\right) + Hilld_i(H), \quad (6)$$

$$Hillk_i(H) = \lambda_i + \sum_h \sigma_{i,h} H_h, \quad (7)$$

$$Hilld_i(H) = \delta_i + \sum_h \rho_{i,h} H_h, \quad (8)$$

$$Y_i(X) = g(Hill_i(X, H)) \quad (9)$$

where  $g(x)$  is a unit step function.  $\lambda_i$  and  $\delta_i$  are constant parameters of cell  $i$  and  $\sigma_{i,h}$  and  $\rho_{i,h}$  represent influences of hormone  $h$  on the hill-function of the cell.

The output of a hill-function that is produced based on inputs to the cell can be summarized as:

$$Y_i = g\left(\left(\lambda_i + \sum_h \sigma_{i,h} H_h\right) \times f\left(\sum_j \left[\left(\beta_i + \sum_h \eta_{i,h} H_h\right) \times f\left(\left(\theta_{i,j} + \sum_h \phi_{i,j,k} H_h\right) X_{i,j}\right) + \left(\alpha_i + \sum_h \kappa_{i,h} H_h\right)\right] + \left(\delta_i + \sum_h \rho_{i,h} H_h\right)\right)\right) \quad (10)$$

The output of the cell then is calculated as a factor of the output of the hill-function as:

$$output_i = neurality_i \times Y_i \quad (11)$$

The overall amount of hormone  $h$  in the system is calculated as follows:

$$H_h = \sum_i H_{i,h}, \quad (12)$$

$$H_{i,h} = glandity_{i,h} \times Y_i \quad (13)$$

where  $H_{i,h}$  is the share of cell  $i$  in production of hormone  $h$  and  $glandity_{i,h}$  is a parameter representing the production factor of hormone  $h$  in the cell.

By deactivating the parameters of different modules of this system, e.g. net-function, we get simplified versions of the system.

### The task

To test, if the proposed model has features, that differ from a “non-emotional” neural network, we developed a task, to test the very basic features of the system.

The implemented task is to solve the following equation:

$$output(A, B) = \begin{cases} A & \text{if } A + B > 0.5 \\ 0 & \text{otherwise} \end{cases} \quad (14)$$

A simplified version of EMANN which uses the hill-function is implemented. A population of randomly generated ANNs and a population of randomly generated EMANNs are evolved for the task. The experiment is repeated for 100 independent runs in each case. The structures of the implemented ANN and EMANN are represented in Figure 3. The genomes are a sequence of parameters for each network and a standard genetic algorithm is used as the evolutionary algorithm. Experimental settings are summarized in Table 1.

Table 1: Experimental settings

|                       |                      |
|-----------------------|----------------------|
| number of cells       | 4                    |
| number of synapses    | 4                    |
| number of hormones    | 1                    |
| active-modules        | <i>hill-function</i> |
| population size       | 250                  |
| number of generations | 25000                |
| mutation rate         | 0.7                  |
| mutation probability  | 0.2                  |

Figure 3: Network structures for the given task. The ANN, as well as the EMANN, have two inputs, and one neural output (as described in the section). Besides this, the EMANN has a hormonal output, that influences the *hill-function* (equ. 7) of all cells in the network.

### Results

The test of the EMANN concept in the task described above showed that the EMANN is able to generate higher fitness values in an evolutionary run comparing an ANN. The experiment was performed several times. An exemplary evolutionary run is depicted in figure 4. It shows, that both ANN and EMANN have a very fast increase of the fitness level reached within the first few generations. ANN reaches its maximum fitness of about 0.6 with the first few generations, while EMANN increases its reached fitness throughout the whole experiment.

Repeating the experiment several times showed that the better results from EMANN paradigm in comparison to the used state-of-the-art ANN (see figure 5 for more details) is statistically significant.

### Discussion

In his work Fellous (Fellous, 2004) argues that the implementation of emotions in an artificial system may not only be useful as a model for emotional processes in real-world lifeforms, but also may have advantages for purely artificial systems. As depicted in figure 5 we can show these assumptions are valid for the test described in using an EMANN and comparing it to a state-of-the-art ANN.

Regarding the biological counterparts, it is interesting from a biological point of view that state of the art ANN paradigms in most instances omit the fact, that in biological neural control systems are massively modulated, not to say ‘controlled’ by emotions. This phenomenon can be found in both, ‘regular’ emotions (as already mentioned above) or emotions based on diseases (e.g., depression, as described by Harding et al. (2004)). These modulations of the nervous system and the associated behaviour can vary from a biasing of the behavioural pattern, to a complete change of be-

Figure 4: Exemplary evolutionary run of EMANN and ANN. It shows that the EMANN is able to solve the task better than the ANN. The task to solve is described in section . Curves indicate the maximum fitness value of every generation. Fitness is calculated according to equ. 14

haviour. Due to this, emotions can be understood as a kind of biological task-selection mechanism, from an engineering point of view. In literature the concept of emotions has been tested before, but always with a strict separation of hormonal system (e.g. hormonal glands) and the neural system: Gadanho and Hallam (2002) proposed a hormonal-neural system, which is described as a complex multilevel model, consisting of different compartments for cellular structures, neuromodulators and emotional activities. Neal and Timmis (2003) and Timmis et al. (2009) showed a system, in which the hormones interact with the neural system on synaptic level, but the hormone glands are a unit on its own on the input level of the system, with no ability to be influenced directly from the ANN. In the proposed EMANN paradigm, all actions and interactions, be it neurological, hormonal, hormone-gland related, neuromodulatory or emotional, take place on the level of cells and cellular interactions. Especially the ability of a cell to communicate with other cells on a local level (via neurotransmitters/synapses) or on a global level (via hormones) allows more complex activity patterns than a state of the art ANN. Further the cells in an EMANN have the ability not only to exchange information between cells (equ. 9) but also to send commands regarding changes in the information processing within the network (equ. 13) to groups of other cells within the EMANN. This results in a control system, which has the ability to modulate parts of the information processing system by itself, depending on the input of the EMANN.

Regarding the suggestions for the design of robot-emotions of Fellous, described in (Fellous, 2004), are re-

Figure 5: Maximum fitness values of last generation of 100 independent runs with 25000 generations. It shows that the EMANN performs significantly better in the given task compared to an ANN (\*: $p < 0.05$ ; Wilcoxon signed-rank test, unpaired data, "two.sided"-hypothesis, program used for statistical analysis: "R"). Box-plots indicate median and quartiles, whiskers indicate minimum and maximum, circles indicate outliers. Fitness is calculated according to equ. 14

flected in our work:

- *Emotions should not be implemented as a separate, specialized module in charge of computing an emotional value on some dimension.* In the EMANN paradigm hormone glands and neural cells are interlinked on a cellular level. As displayed in figure 2, a cell can act as a neural cell (equ. 9) as well as a hormone gland (equ. 13).
- *Emotions should not simply be the result of cognitive evaluations.* In an EMANN the emotions are the result of the interplay of neural activity and the interaction of hormones (by the modulation of neural cells and glands). The actual level of hormones are the outcome of a complex self-organising feedback system.
- *Emotions are not linear (or non linear) combinations of some pre-specified basic emotions.* The hormones in the EMANN paradigm do not represent any predefined emotions. Hormones act as neuromodulators, which change the functionality of the controller (in this case a neural network). This modulation can be understood as emotion.
- *Emotions should be allowed to have their own temporal dynamics, and should be allowed to interact with one another.* In an EMANN the emotions are an effect of the hormone levels, which are a result of the collective gland activity of all EMANN cells. This way the temporal dynamics of the emotion can be at least of the same dimension

of the neural cells, or much lower, depending from the degree and kind of neural linking of the hormone gland cells. Please note, that in the EMANN paradigm, the temporal dynamic of the hormones can not be higher than the temporal dynamics of the neural cells, but it can be equal or lower. The interaction of hormones takes place via the cells, which are receptors of hormones as well as emitters of hormones.

The results, depicted above show, that the EMANN for the given task is able to outperform an ANN significantly (figure 5). The task selected for this test was, from the authors point of view, the most simple possible, to show the abilities of the EMANN in a well defined small scale experiment.

## Conclusion and Outlook

Our work presents the first results of investigations in a model of emotions in an neural network, the Emotional Artificial Neural Network (EMANN). The EMANN is a development based on state of the art artificial neural networks (ANN, for an overview see (Jain et al., 1996)), improved by the ability to get modulated in its functionality by emotions. The emotions are implemented according to biological examples, inspired by the ideas presented in (Fellous, 2004). It showed, that an EMANN is able to outperform a state-of-the-art ANN in the given test. This shows, that the simulated emotions can have a positive effect on the performance of the ANN.

This paper is the first one in a row of investigations about the features of emotions in artificial neural networks. In the next step we will investigate, how learning algorithms based on emotions (inspired from the biological counterparts) can be used with an EMANN controller. We plan to investigate, how this system of neural, and hormonal feedbacks interacts under conditions of a changing environment, and how given evolutionary constraints (e.g., changing environments on an evolutionary time-scale) change the behaviour of the evolved EMANN controlled agents in complex environments. We further want to investigate, if the effect of genetically fixation of behaviour ("Baldwin effect" (Baldwin, 1896)) is influenced by the presence of emotions in the control system.

To investigate the evolutionary development of neural tissues and brain structures in an artificial system we plan to combine the EMANN paradigm with algorithms, that are able to shape morphological structures and controller structures in an evolutionary manner (Thenius et al., 2009b; Schmickl et al., 2011b; Kernbach et al., 2009; Thenius et al., 2010; Dauschan et al., 2011; Thenius et al., 2009a). To what extend the interplay of abiotic environment, social environment and behaviour can change the shape of brains in an artificial system (as described for biological systems, e.g., by Breedlove and Arnold (1980)) will be investigated in the

next step. We also plan to investigate the influence of emotions on the self-healing abilities (Thenius et al., 2011) of a controlling tissue in an artificial structured controller of an EMANN system.

One goal of the research in EMANN will be to investigate how the concept of emotions can be used in single autonomous robots or swarms of robots in complex environment (e.g., for (Schmickl et al., 2011a; Kernbach et al., 2008)). We plan, on a robotic swarm level, to share artificial hormones between spatially close agents (e.g., via short-range communication), what can result in a spatial organised task allocation or even spatially organised calculation processes based on interacting hormone levels inside a (big) swarm. The conditions, under which hormones are emitted within the swarm, and how the controllers of the swarm react to the given hormone level, can be as well engineered by hand, as well as shaped by an artificial evolutionary process.

Another goal is to investigate the role of emotions in the development of complex behaviours in an eusocial system, e.g., behaviours comparable to the BEECLUST algorithm (Schmickl et al., 2008; Bodi et al., 2012; Hereford, 2011).

To what extend the proposed system can be used as a model for biological and psychological processes (as suggested by Fellous in (Fellous, 2004)) will also be investigated in the future.

### Abstract

The Negative Selection Algorithm is an immune inspired algorithm that can be used for different purposes such as fault detection, data integrity protection and virus detection. In this paper we show how the Negative Selection Algorithm can be adapted to tackle the similar image search problem: given a target image, images from a large database similar to the query have to be detected. Results of our experimental analysis indicate that the proposed algorithm is capable of detecting images similar to a target (self) image, given the right detectors. Source code and data used in the experiments are available on request.

### Introduction

The increasing storage capacity of modern disk devices allows to collect and distribute large-scale image data efficiently. As a consequence, an enormous amount of images is generated and made publicly available. This phenomenon has boosted research on search for similar images. Search by image as implemented for example by Google (2013) allows one to discover all sorts of content that is related to a specific image. Search results include similar images, webpages and even sites that include that picture. The main challenge is to develop efficient methods for achieving high image retrieval quality. Many techniques have been proposed for this task (see for instance Smeulders et al. (2000)).

A crucial step in image similarity search is the comparison of two images, typically a target image and an image from the database. Image distance measures are used for this task. An image distance measure compares the similarity of two images in various dimensions such as color, texture, shape, and others.

Our goal is to investigate whether a negative selection algorithm with simple techniques for comparing images is suitable for tackling the Image Similarity Search problem.

To this aim, we designate the target image as self data and then create detectors for anything that is not self. We consider a simple setting where color is used as the only feature to define distances between images. Color does not depend on image size or orientation, hence is easy to handle.

In order to analyze whether NSA is applicable to Image Similarity Search, two sets of experiments are conducted. First, we consider a publicly available dataset of holiday images and assess manually how good the results of NSA are. Second, we construct a specific dataset consisting of three classes and manually associate a class to each image. We perform a leave-one-out cross validation on the dataset. Specifically for each image, we consider it as target image and use the rest of the data to search for similar images. Then average precision of each target is computed and the mean results are analyzed.

Results of experiments indicate the suitability of negative selection for this task, considering the fact that we use only color as feature. We would like to stress that the goal of this paper is not to try to compete with algorithms such as those used by Google, but to show that NSA can be applied to search by image.

### Background

The original negative selection algorithm is inspired by the way that natural immune systems distinguish self from other (Forrest et al., 1994). When the body encounters a virus or any cells that do not belong to the body's own cells, white blood cells are sent out to react to this and to destroy the foreign cells. A specific type of these blood cells are the so-called T-Cells. One of the things these might do is destroy cells infected by viruses. However, one interesting property of these cells is that they somehow know how to discriminate between foreign tissue and your own body. The process that leaves only these T-cells alive is called negative selection (Dasgupta et al., 2011).

The T-cells are formed in the thymus. The thymus is a small organ that is located in front of the heart and near the sternum. In this organ there are a lot of proteins that belong to the body itself. When a T-cell is just formed it might attack these proteins. These immature T-cells that strongly bind to these self-antigens undergo a controlled programmed cell death, referred to as apoptosis (Stibor et al., 2005). We will not go into the details of this mechanism. What is important to observe is that generally only T-cells that attack

foreign antigens leave the Thymus. Thus, the T-cells that survive this process should be nonreactive to self-antigens, but attack antigens they don't know instead.

The Negative Selection Algorithm (NSA) (Forrest et al., 1994) is inspired by a main mechanism in the thymus that produces a set of mature T-cells capable of binding only to non-self antigens. Many variants of this mechanism exist, often exploiting other natural elements, see for instance Gao et al. (2008) and Shapiro et al. (2005). NSA has many applications, most notably in the field of fault and intrusion detection (Dasgupta and Forrest, 1995; Kim and Bentley, 2001; Taylor and Corne, 2003; Dasgupta et al., 2004). Another typical application is anomaly detection (Dasgupta and Majumdar, 2002; González and Dasgupta, 2003).

NSA basically consists of two steps, as shown schematically in Figure 1 and 2 for the scenario where the integrity of a data file or string has to be protected (Forrest et al., 1994). Using NSA, the first step then is to generate a set of detectors. Each detector is a string that does not match a predetermined substring of the protected data. For matching, usually a partial matching rule is defined, because it can be extremely rare that random strings that are generated exactly match the source data, even if these strings are small.

Figure 1: Detector Generation, taken from Forrest et al. (1994)

The second step is to continually monitor the data by comparing them with the detectors. If a detector is ever activated, a change is known to have occurred.

Although this approach might seem too simple to work, it is rather effective: a fairly small set of detector strings has a very high probability of noticing a random change to the original data (Forrest et al., 1994).

### NSA for image similarity search

We want to apply the NSA to image similarity search. To this aim, we designate the target image as self data and then create detectors for anything that is not self. For this to work we try to match pixels or pixel groups on each other and use the fraction of matching groups as a similarity measure. A match can be determined via a direct pixel to pixel comparison, but also via a similarity measure, like the one that will

Figure 2: Monitor protected data, taken from Forrest et al. (1994)

be explained later.

Once we have generated detectors implementing these methods we can match them on the data set and retrieve dissimilarity values, which can then be inverted and used to identify images that are very similar to the target image.

In effect, we're trying an alternative approach to achieve what Google does with reverse image search. You can upload a picture to Google and Google returns a list of similar images on the web (Google, 2013). In our case we adapt the negative selection algorithm to accomplish this.

### Framework

The NSA algorithm is implemented using C++, because we needed to load and clear many Gigabytes of images in the RAM and this can be done efficiently in C++. It's also object-oriented, so producing a framework was easier.

To apply the algorithm we wrote a framework that handles file input and output. It includes a Detector super-class, which has initialization and detection functions by default. Any detector we implemented was able to provide implementations and extensions to this detector class, while maintaining the basic functionality needed for the algorithm.

Figure 3 illustrates the proposed method. The NSA algorithm (in the center) receives images (the target image and the database of images for searching) from an image-reader class. It then applies its detectors to those images to get a similarity measure.

### Detectors

The algorithm is strongly dependent on the detectors that are created. Each of the detectors implements a basic measure of similarity between two images. The idea here is that, with enough of these detectors, we can get a reasonable approximation for the actual similarity by combining the advantages of each detector and by canceling out the downsides of each single similarity measure. The advantage is then that running these simple detectors, possibly in parallel, would

Figure 3: NSA framework

be much cheaper than running more complicated measures, such as those based on compact data structures and Earth Movers Distance (see e.g. Lv et al. (2004)).

**Direct pixel similarity (DPS)** One of the first ideas that comes to mind when implementing a detector is the direct pixel similarity (DPS). In this case we are working at the pixel level. So the most simple and obvious similarity measure is a direct RGB comparison of each pixel. If the pixels are the same they match, if they are different they do not match. All the matches are counted and normalized to one.

Obviously this is not a very good detector since it is rare that many pixels in a picture match exactly with the target picture. There might be subtle changes in brightness or other minor differences that are barely visible and that will negatively influence such similarity measures.

Therefore we weaken the similarity match by considering a range for each pixel value  $v$ , such that we still agree on a match if the value  $v$  of each color component is in the range  $[v - r, v + r]$ , for a given parameter  $r$ .

Furthermore, we define a match on a group of  $n$  by  $n$  pixels if for a certain threshold  $t$ ,  $t$  pixels in a group of the target image match the foreign image. In the end we count all matches and divide by the total amount of pixel groups that were compared to get the final similarity measure. In Figure 4 we can see how the proposed matching pixel group comparison works with  $n = 3$ ,  $t = 5$ , and  $r = 0$ . The pixels in row 1 up to 3 and column 1 up to 3 are directly compared. Every pixel in this group has the same value so the match count is 9. This is bigger than the threshold  $t = 5$  so these pixel groups match.

Figure 4: Matching pixel group comparison with  $n = 3$ ,  $t = 5$ 

Figure 5 shows an example of a pixel group that does not

match. The pixels in row 4 up to 6 and column 1 up to 3 are directly compared. But the pixels in row 4 and 5 have different values so there are only 3 pixels that match. Since  $3 < t$ , these pixel groups do not match.

Figure 5: Non-matching pixel group comparison with  $n = 3$ ,  $t = 5$ 

**Average color difference similarity (ACDS)** Another measure we consider incorporates the summed color difference of each color component. By dividing this summed difference by the absolute maximum difference possible, we get a similarity measure between 0 and 1: the average color difference similarity (ACDS).

The same matching rule as in the previous method can then be used on a group of pixels, but in this case we define the threshold  $t$  to be a value between 0 and 1. In this way we are basically saying that a pixel group of the foreign image has to match for  $100t$  percent with the target image.

This measure has as advantage that its a lot more flexible: if a picture is similar in part to the target image, but different in some others, it might still get a high score. A disadvantage is that, since comparing colors is not that easy, you can get some results, where colors are considered similar even though to our eyes they might not be. For instance, brown is very similar to grey from pure values, but to the human eye it would be different.

## Application

In our application we use the holiday data set (Jegou et al., 2008) that consist of 812 pictures that were made by people on their holidays, see Figure 6 for a snapshot. The collection is applicable to the problem at hand because it contains clusters of similar images, for example for outdoor environments, while maintaining a very broad category, in contrast to other datasets which are either too specific or too general (Toet et al., 2001; Deng et al., 2009; Chen et al., 2009). Indoor surroundings with similar characteristics can also be found, so we were able to identify similar images from this set. A downside of this dataset is that the original images vary in width and height so additional preprocessing on the data set had to be done to improve performance in both run-time and quality. We have resized all images to a smaller, equal size before the algorithm was run. Manual inspection of the results was used to assess their quality.
